(Dated: February 8, 2008)

A method is presented to obtain the canonical-form solutions of the HFB equation for atomic nuclei with zero-range interactions like the Skyrme force. It is appropriate to describe pairing correlations in the continuum in coordinate-space representations. An improved gradient method is used for faster convergences under constraint of orthogonality between orbitals. To prevent high-lying orbitals to shrink into a spatial point, a repulsive momentum dependent force is introduced, which turns out to unveil the nature of high-lying canonical-basis orbitals. The asymptotic properties at large radius and the relation with quasiparticle states are discussed for the obtained canonical basis.

I. INTRODUCTION

Pairing correlations play an essential role in the determination of the ground-state structure of the vast majority of atomic nuclei. Among its treatments, an easy but still enough accurate one is to consider only single-particle states near the Fermi level while the effects of the other states are assumed to be absorbed in the strength of an effective pairing interaction. In such a treatment, our experiences in Hartree-Fock(HF)+BCS calculations suggest that at least half of a major shell above the Fermi level must be considered for meaningful estimations. As a consequence, one has to explicitly consider positive-energy states if the Fermi level of neutrons is higher than the negative of half of the major shell spacing ($\sim \frac{41}{2}A^{-1/3}$ MeV). This condition applies to about half of the 10^4 nuclides which exist between proton and neutron drip lines in the nuclear chart, not only to nuclei near the neutron drip line or outside the s-process path. Thus there are plenty of necessities for theoretical frameworks which can describe pairing correlations involving the continuum states.

If the pairing correlation significantly involves the continuum states, the HF+BCS approximation becomes inadequate because the occupation of unbound HF orbitals leads to the unwanted dislocalization of the nucleon density. This is a serious problem in coordinate-space treatments, which is more favorable to describe loosely bound systems like drip-line nuclei than expansions in harmonic-oscillator eigenstates (except the transformed oscillator basis of Ref. [1]). The reason why a dislocalized solution becomes the variational minimum is that, in order to separate the variational equations into HF and BCS, one has to neglect the effects that the matrix elements of pair-scattering processes are affected by the changes in the wave functions of the orbitals involved [2]. To fully

take into account these effects leads to the Hartree-Fock-Bogoliubov (HFB) equation, with which the density is localized whenever the Fermi levels are negative [3, 4].

The HFB method in the coordinate space was first formulated using the quasiparticle states and solved for spherically symmetric states in Ref. [3]. Although spherical solutions can be obtained easily with present computers (for zero-range forces), deformed solutions are still difficult to obtain because there are quite a large number of quasiparticle states even for a moderate size of the normalization box (i.e., the cavity to confine the nucleons to discretize the positive-energy single-particle states). An orthodox approach to face this difficulty is the two-basis method [5, 6, 7, 8, 9], in which the quasiparticle states are expanded in bound and unbound HF orbitals. This method requires heavy numerical calculations because there are a pile of unbound HF orbitals below an energy cut-off of even only a few MeV.

An alternative approach is the canonical-basis HFB method. According to the Bloch-Messiah theorem [10], every HFB solution obtained as the vacuum of a set of Bogoliubov quasiparticles has an equivalent expression in terms of a BCS-type wave function. The single-particle states appearing in this expression are called the HFB canonical basis. In the canonical-basis HFB method, one obtains the solution in the canonical form without using the quasiparticle states. This method appeared originally in Ref. [11] to obtain spherical solutions. However, there are no severe difficulties in obtaining HFB solutions for spherical nuclei using any other methods. Applications to deformed nuclei have been done by us [8, 12, 13, 14] using a three-dimensional Cartesian mesh representation [15]. Incidentally, a different line of application is also found in literature [18].

Let us explain the advantage of the canonical-basis method over the two-basis method concerning the treatment of the pairing in the continuum using Fig. 1. On both sides of the figure, the ordinate represents the expectation value of the mean-field (HF) energy, while the abscissa stands for the radius r from the center of the nucleus. ϵ_c and ϵ_F mean a cut-off energy and the Fermi

FIG. 1: Comparison between the HF orbitals and the HFB canonical-basis orbitals. See text for explanations.

level, respectively. On the left-hand side, the wavy horizontal lines stand for energy levels and their spatial extent for the HF potential denoted by a solid curve. The wave functions of positive energy states extend to the wall of the box and their level density is much larger than that of negative energy states. In the two-basis HFB method, one has to mix these positive-energy orbitals to construct localized canonical-basis orbitals, which is a numerically demanding task. On the right-hand side, the wavy lines represent the HFB canonical-basis orbitals. Unlike HF orbitals, they are spatially localized for both negative and positive energies. Because of this localization, the level density is much smaller than the unbound HF orbitals. Therefore, one needs much less orbitals. More specifically, the number of necessary single-particle states to describe the HFB ground state of a nucleus is proportional to the volume of the nucleus in the canonical-basis method while it is related to the volume of the normalization box in the other methods. Incidentally, with the dash curve, we suggest the existence of some potential which binds the high-lying canonical-basis orbitals. The identity of this potential is unveiled in Sec. VI B.

In this paper we formulate the canonical-basis HFB method on a cubic mesh and develop an efficient gradient method to obtain its solutions. In order to decrease unphysical influences of high-momentum components due to zero-range interactions, we introduce a momentum dependent term to the pairing interaction and show how it suppresses a problematic behavior of wave functions peculiar to the canonical-basis HFB method. As a byproduct, we show a clear way to understand the nature of high-lying canonical-basis orbitals.

The contents of this paper is as follows. In sections II – V, we give the formulation and general considerations. Discussions using results of numerical calculations are collected in section VI. Conclusions are given in section VII. In Appendix A we examine the errors due to the mesh representation and the box boundary condition. Appendix B gives a model analysis of the problem peculiar to the method, i.e., a phenomenon that canonical-basis orbitals collapse to a spatial point once their occupation probabilities fall below some critical value when pure delta-function forces are used.

Some of the contents of this paper have already been discussed in our earlier reports [8, 12, 13, 14]. For example, Ref. [8] includes the first report on the canonical-basis HFB method on a cubic mesh. Refs. [13, 14] re-

ported on the discovery of the point-collapse problem and the tests of the state-dependent cut-off factors and pairing-density-dependent forces as the remedies. In this paper we have rewritten those contents to include the momentum-dependent interaction and, by including the rewritten contents, organized the formalism for consistency and selfcontainedness. All the numerical calculations shown in this paper have been performed using the renewed form of the interaction.

Incidentally, some important parts of those reports are not repeated in this paper. The examples are an analysis of the spherical two-basis method concerning the precision of density tails [8] and numerical demonstrations of the point collapses of high-lying orbitals [14].

II. HFB IN THE CANONICAL REPRESENTATION

To begin with, let us formulate HF and HFB methods in the coordinate-space representation in order to elucidate the difficulty of the quasiparticle-based HFB method compared with the HF method and to propose its possible solution in terms of the canonical-basis HFB method. For the sake of simplicity, we consider only one kind of nucleons in this section. The number of that kind of nucleons are designated by N . The z -component of the spin of a nucleon is represented by s ($= \pm \frac{1}{2}$).

In HF, one should minimize $\langle \Psi | H | \Psi \rangle$ among all the N -body single Slater-determinant states,

$$|\Psi\rangle = \prod_{i=1}^N a_i^\dagger |0\rangle, \quad (1)$$

$$a_i^\dagger = \sum_s \int d^3r \psi_i(\mathbf{r}, s) a^\dagger(\mathbf{r}, s), \quad (2)$$

by varying $\{\psi_i\}_{i=1,\dots,N}$ under orthonormality conditions $\langle \psi_i | \psi_j \rangle = \delta_{ij}$. The operator $a_i^\dagger$ creates a nucleon with a wave function $\psi_i(\mathbf{r}, s)$. The ket state $|0\rangle$ stands for the state in which no nucleons exist. The distribution function of the number density of the nucleons is related to the single-particle wave functions as

$$\rho(\mathbf{r}) = \sum_{i=1}^N \sum_s |\psi_i(\mathbf{r}, s)|^2. \quad (3)$$

There is arbitrariness in the selection of $\{\psi_i\}$ as for unitary transformations among them. ψ_i are called HF orbitals when they diagonalize the HF Hamiltonian.

In HFB, the solution takes the following form,

$$|\Psi\rangle = \prod_{i=1}^{N_B} b_i |0\rangle, \quad (4)$$

$$b_i = \sum_s \int d^3r \{ \phi_i^*(\mathbf{r}, s) a(\mathbf{r}, s) + \varphi_i^*(\mathbf{r}, s) a^\dagger(\mathbf{r}, s) \} \quad (5)$$

where b_i is the annihilation operator of a positive-energy Bogoliubov quasiparticle with two types of amplitudes $\phi_i(\mathbf{r}, s)$ and $\varphi_i(\mathbf{r}, s)$ for particle-like and hole-like parts of the excitation. N_B is the number of the basis states of the representation used and is by far larger than N . One should vary $\{\phi_i, \varphi_i\}_{i=1, \dots, N_B}$ under an orthonormality condition

$$\sum_s \int \{\phi_i^*(\mathbf{r}, s)\phi_j(\mathbf{r}, s) + \varphi_i^*(\mathbf{r}, s)\varphi_j(\mathbf{r}, s)\} d^3r = \delta_{ij}, \quad (6)$$

and a constraint on the expectation value of the number of nucleons,

$$\int \rho(\mathbf{r}) d^3r = N, \quad (7)$$

where the nucleon density for state (4) is expressed as

$$\rho(\mathbf{r}) = \sum_{i=1}^{N_B} \sum_s |\varphi_i(\mathbf{r}, s)|^2. \quad (8)$$

The essential difference between HF and HFB lies in the number of necessary single-particle wave functions. It is N in the former and $2N_B$ in the latter. Obviously, the latter is much larger.

Owing to the Bloch-Messiah theorem [10], the state (4) can be transformed (as for the ordinary ground states of even-even nuclei) into the following form,

$$|\Psi\rangle = \prod_{i=1}^{N_w} (u_i + v_i a_i^\dagger a_{\bar{i}}^\dagger) |0\rangle, \quad (9)$$

$$a_{i(\bar{i})}^\dagger = \sum_s \int d^3r \psi_{i(\bar{i})}(\mathbf{r}, s) a^\dagger(\mathbf{r}, s), \quad (10)$$

where $a_i^\dagger$ and $a_{\bar{i}}^\dagger$ create a nucleon with wave functions $\psi_i(\mathbf{r}, s)$ and $\psi_{\bar{i}}(\mathbf{r}, s)$, respectively, which are called the canonical basis of the HFB vacuum $|\Psi\rangle$. They may be called the natural orbitals [11] instead, because they are the eigenstates of the one-body density matrix. In this paper, we often call them canonical-basis orbitals or canonical orbitals. It is required $N_w = \frac{1}{2}N_B$ for the exact equivalence between Eqs. (4) and (9) to hold in general.

In this paper we assume that $|\Psi\rangle$ is invariant under the time reversal operation. In this case, ψ_i and $\psi_{\bar{i}}$ are the time-reversal state to each other and only one of them has to be considered explicitly in the variational procedure. The nucleon density can be expressed as

$$\rho(\mathbf{r}) = 2 \sum_{i=1}^{N_w} \sum_s v_i^2 |\psi_i(\mathbf{r}, s)|^2, \quad (11)$$

in the time-reversal invariant case.

In order to obtain solutions expressed in the canonical form without using the information of the quasiparticle states, one should vary $\{\psi_i, u_i, v_i\}_{i=1, \dots, N_w}$ under three kinds of constraints, i.e., the orthonormality condition,

$$\langle \psi_i | \psi_j \rangle = \sum_s \int \psi_i^*(\mathbf{r}, s) \psi_j(\mathbf{r}, s) d^3r = \delta_{ij}, \quad (12)$$

a condition on the expectation value of the number of nucleons,

$$2 \sum_{i=1}^{N_w} v_i^2 = N, \quad (13)$$

and the normalization of the u - v factors, $u_i^2 + v_i^2 = 1$.

Reinhard *et al.* wrote that the advantage of the representation (9) over (4) is that one has to consider only a single set of wave functions $\{\psi_i\}$, not a double set $\{\phi_i, \varphi_i\}$ [11]. In our opinion, however, one may expect much greater benefit from the canonical-basis representation. Namely, i may be truncated as $i \leq N_w = \mathcal{O}(N) \ll \frac{1}{2}N_B$ to a very good approximation.

The reason is the localization of the density. The density distribution of HFB solutions can be shown to behave asymptotically for large r as

$$\rho(r) \sim \left(\frac{e^{-\kappa r}}{r} \right)^2, \quad \kappa \geq \frac{\sqrt{-2m\epsilon_F}}{\hbar}, \quad (14)$$

as far as the Fermi level ϵ_F is negative [3], where m is the nucleon mass. Consequently, ψ_i appearing on the right-hand side of Eq. (11) must be a localized function as $\rho(\mathbf{r})$ on the left-hand side. On the other hand, the orthogonality relation (12) restricts the number of wave functions which can exist in the vicinity of the nucleus. Therefore the number of canonical orbitals cannot be very large. In mesh representations, N_B is proportional to the volume of the box while N_w is proportional to the volume of the nucleus. The latter is $10^{-1} - 10^{-2}$ times as small as the former in typical calculations.

Situation is quite different in the quasiparticle formalism: The number of quasiparticle states is proportional to the volume of the box. This is because the localization of the density demands only that of φ_i through Eq. (8) while ϕ_i does not have to be localized in general. The orthogonality condition (6) involves both φ_i and ϕ_i . This enables many quasiparticle states having similar φ_i to be orthogonal to each other by differing their ϕ_i .

III. MEAN FIELDS FOR ZERO-RANGE INTERACTIONS

In this paper, we employ the Skyrme interaction [2, 16], which is a density- and momentum-dependent zero-range interaction:

$$\begin{aligned} \hat{v} = & t_0(1 + x_0 P_\sigma) \delta + \frac{1}{2} t_1(1 + x_1 P_\sigma) (\mathbf{k}^2 \delta + \delta \mathbf{k}^2) \\ & + t_2(1 + x_2 P_\sigma) \mathbf{k} \cdot \delta \mathbf{k} + \frac{1}{6} t_3(1 + x_3 P_\sigma) \rho^\alpha \delta, \end{aligned} \quad (15)$$

where P_σ is the spin exchange operator, $\delta = \delta(\mathbf{r}_1 - \mathbf{r}_2)$ with $\mathbf{r}_1$ and $\mathbf{r}_2$ the position vectors of the interacting two nucleons, ρ is the nucleon density at $\mathbf{r}_1$ ($= \mathbf{r}_2$), and

$$\mathbf{k} = \frac{1}{2i} (\nabla_{\mathbf{r}_1} - \nabla_{\mathbf{r}_2}). \quad (16)$$

$\hbar\mathbf{k}$ is the relative momentum between the two nucleons. Since it is hermitian under the box (vanishing and periodic) boundary conditions, we have not specified in which way (to bra or ket states) it operates in Eq. (15) unlike in, e.g., Ref. [2]. Zero-rangeness makes the mean-field potentials local, which is an essential advantage for coordinate-space solutions.

Among the terms of the Skyrme force, those with strength parameters t_0 , t_1 , and t_3 act only on s-wave relative motions. The term with t_1 serves to take into account the effects of the finite-rangeness in terms of the lowest order momentum dependence, while the term with t_3 expresses a density dependence. The term with strength t_2 acts on relative p-wave states through a different form of momentum dependence. Note that the isospin channel ($T=0$ or 1) is uniquely determined through the requirement of the two-body antisymmetry. Owing to the p-wave as well as the s-wave interaction terms, the Skyrme force can act on all the four kinds of spin-isospin channels.

The complete Skyrme interaction includes a spin-orbit term $iW(\boldsymbol{\sigma}_1 + \boldsymbol{\sigma}_2) \cdot \mathbf{k} \times \delta\mathbf{k}$, which we have excluded from Eq. (15). This elimination decreases the size of the numerical calculations by a factor of four (two from spin up and down components, another two from real and imaginary parts of the spatial wave function). Due to this size reduction, we can perform very severe tests of the canonical-basis HFB method by, e.g., taking into account unusually many canonical orbitals or expressing wave functions on a very large mesh.

As the parameters of the force, we choose the SIII set [17] except for the spin-orbit term, i.e., $t_0 = -1128.75 \text{ MeV fm}^3$, $t_3 = 14000 \text{ MeV fm}^{3+3\alpha}$, $\alpha = 1$, and $W = 0$. As for the parameters appearing in the momentum dependent terms, the following two combinations are sufficient to treat $N = Z$ even-even nuclei,

$$f_1 = \frac{1}{16} (3t_1 + 5t_2 + 4t_2x_2), \quad (17)$$

$$f_2 = \frac{1}{64} (-9t_1 + 5t_2 + 4t_2x_2), \quad (18)$$

whose values are $f_1 = 44.375 \text{ MeV fm}^5$ and $f_2 = -62.969 \text{ MeV fm}^5$.

As is usually done, we employ different parameters between the mean-field and the pairing interactions. We use the following interaction for the pairing channel,

$$\hat{v}_p = v_p \frac{1 - P_\sigma}{2} \left[\left\{ 1 - \frac{\rho}{\rho_c} - \left(\frac{\tilde{\rho}}{\tilde{\rho}_c} \right)^2 \right\} \delta - \frac{1}{2k_c^2} (\mathbf{k}^2 \delta + \delta \mathbf{k}^2) \right], \quad (19)$$

where v_p is the strength and $\frac{1}{2}(1 - P_\sigma)$ is the projector into spin-singlet states. Terms in the braces represent dependences on particle and pairing densities. The interaction becomes repulsive where $\rho > \rho_c$ or $\tilde{\rho} > \tilde{\rho}_c$. For the particle-density dependence, we use $\rho_c = 0.32 \text{ fm}^{-3}$ to vanish the volume-changing effect[19] (This choice, twice of the matter density, is also recommended for a different

reason [20].) The dependence on the pairing density $\tilde{\rho}$ (to be defined by Eq. (26)) has been introduced in Ref. [13] to prevent unphysical behaviors of high-lying canonical orbitals discussed in Appendix B. This term is squared because $\tilde{\rho}$ can become negative in principle. Except in Appendix B, we use $\tilde{\rho}_c = \infty$. The momentum dependent term acts on s-wave relative motions and quenches interactions between nucleons in high-momentum states. The interaction vanishes at relative momentum k_c at low-density points. If $\tilde{\rho}_c = k_c = \infty$, this pairing force is reduced to that introduced in [19]. The typical values of the parameters are $v_p = -1000 \text{ MeV fm}^3$ and $k_c = 2 \text{ fm}^{-1}$ but different values are also used.

The $S=0$ and $T=1$ part of the Skyrme force of Eq. (15) may be rewritten as Eq. (19) without the pairing density dependent term. Using different parameterizations between the two forces has an advantage of avoiding confusions.

When one considers both protons and neutrons, the state of the nucleus is usually assumed to be a product of two BCS-type states of Eq. (9), one for the protons and the other for the neutrons:

$$|\Psi\rangle = \prod_{q=p}^n \prod_{i=1}^{N_w^{(q)}} \left(u_{qi} + v_{qi} a_{qi}^\dagger a_{q\bar{i}}^\dagger \right) |0\rangle, \quad (20)$$

where the index q distinguishes between protons (p) and neutrons (n). $a_{pi}^\dagger$ creates a proton having a wave function $\psi_{pi}(\mathbf{r}, s)$ while $a_{ni}^\dagger$ creates a neutron with a wave function $\psi_{ni}(\mathbf{r}, s)$. This product form matches our choice of the pairing interaction of Eq. (19) which acts only on $T = 1$ pairs.

In this paper we treat only $N=Z$ nuclei without Coulomb interaction for the sake of simplicity. In this case, the wave functions are the same between protons and neutrons. Moreover, because the potentials are independent of the spin, the wave functions $\psi_i(\mathbf{r}, s)$ can be factorized into a product of a spin wave function and a real-number function of the position, which we write $\psi_i(\mathbf{r})$ hereafter. More specifically, we assume $\psi_{pi}(\mathbf{r}, s) = \psi_{ni}(\mathbf{r}, s) = \psi_i(\mathbf{r})\delta_{s, \frac{1}{2}}$ and $\psi_{p\bar{i}}(\mathbf{r}, s) = \psi_{n\bar{i}}(\mathbf{r}, s) = \psi_i(\mathbf{r})\delta_{s, -\frac{1}{2}}$.

The isoscalar pairing may take over the isovector pairing in $N \sim Z$ nuclei [21]. Nevertheless, we assume Eq. (20) because the aim of this paper is to examine a method whose most important applications are to the nuclei near the neutron drip line.

Our Hamiltonian H consists of a kinetic energy term and two-body interaction terms. It should be understood that both are expressed in the second quantized form because HFB states do not have a fixed number of particles. The kinetic energy term is $-\hbar^2 \nabla^2 / 2m$ in the one-body expression, for which we assume the mass of a nucleon m to be the average of the proton and the neutron bare masses (m_p and m_n) with an approximate correction factor for the center-of-mass motion of a nucleus of mass

number A :

$$m = \left(1 - \frac{1}{A}\right)^{-1} \frac{m_p + m_n}{2}. \quad (21)$$

For the interaction terms, we use the interaction (15) for the mean-field type contractions and the interaction (19) for the pairing type contractions in evaluating the matrix elements of the two-body interactions using Wick's theorem.

The total energy for the state (20) can be expressed in terms of a single space integral as,

$$E_{\text{tot}} = \langle \Psi | H | \Psi \rangle = \int \mathcal{H}(\mathbf{r}) d^3r, \quad (22)$$

where the integrand is given by

$$\begin{aligned} \mathcal{H} = & \frac{\hbar^2}{2m} \tau + \frac{3}{8} t_0 \rho^2 + f_1 \rho \tau + f_2 \rho \nabla^2 \rho + \frac{1}{16} t_3 \rho^{2+\alpha} \\ & + \frac{v_p}{8} \left[\left\{ 1 - \frac{\rho}{\rho_c} - \left(\frac{\tilde{\rho}}{\tilde{\rho}_c} \right)^2 \right\} \tilde{\rho}^2 - \frac{\tilde{\rho}}{k_c^2} (\tilde{\tau} - \nabla^2 \tilde{\rho}) \right]. \end{aligned} \quad (23)$$

On the right-hand side of the above equation, functions of position $\mathbf{r}$ are

$$\rho(\mathbf{r}) = 4 \sum_{i=1}^{N_w} v_i^2 |\psi_i(\mathbf{r})|^2, \quad (24)$$

$$\tau(\mathbf{r}) = 4 \sum_{i=1}^{N_w} v_i^2 |\nabla \psi_i(\mathbf{r})|^2, \quad (25)$$

$$\tilde{\rho}(\mathbf{r}) = 4 \sum_{i=1}^{N_w} u_i v_i |\psi_i(\mathbf{r})|^2, \quad (26)$$

$$\tilde{\tau}(\mathbf{r}) = 4 \sum_{i=1}^{N_w} u_i v_i |\nabla \psi_i(\mathbf{r})|^2, \quad (27)$$

which are called [3] the (particle) density, the kinetic-energy density, the pairing density, and the pairing kinetic-energy density, respectively.

There is a set of single-particle operators ($\mathcal{H}_i$, h , and $\tilde{h}$) which are useful to obtain mean-field solutions. They can be obtained by taking the functional derivative of E_{tot} with respect to a canonical wave function ψ_i . This turns out to be equivalent to operating a state-dependent single-particle Hamiltonian $\mathcal{H}_i$ to the wave function :

$$\frac{\delta E_{\text{tot}}}{\delta \psi_i} = 4\mathcal{H}_i \psi_i^*, \quad \frac{\delta E_{\text{tot}}}{\delta \psi_i^*} = 4\mathcal{H}_i \psi_i. \quad (28)$$

Here, we have taken the familiar point of view that ψ_i and ψ_i^* can be formally regarded as independent variables, although ψ_i is actually a real function.

One can express $\mathcal{H}_i$, in turn, as a linear combination of state-independent single-particle Hamiltonians as,

$$\mathcal{H}_i = v_i^2 h + u_i v_i \tilde{h}, \quad (29)$$

where h and $\tilde{h}$ are called the mean-field and pairing Hamiltonians. They are given by

$$h = -\nabla \cdot B \nabla + V, \quad (30)$$

$$\tilde{h} = -\nabla \cdot \tilde{B} \nabla + \tilde{V}, \quad (31)$$

with

$$B = \frac{\hbar^2}{2m} + f_1 \rho, \quad (32)$$

$$V = \frac{3}{4} t_0 \rho + \frac{2+\alpha}{16} t_3 \rho^{1+\alpha} + f_1 \tau + 2f_2 \nabla^2 \rho - \frac{v_p \tilde{\rho}^2}{8\rho_c}, \quad (33)$$

$$\tilde{B} = -\frac{v_p}{8k_c^2} \tilde{\rho}, \quad (34)$$

$$\tilde{V} = \frac{v_p}{4} \left[\left\{ 1 - \frac{\rho}{\rho_c} - 2 \left(\frac{\tilde{\rho}}{\tilde{\rho}_c} \right)^2 \right\} \tilde{\rho} - \frac{\tilde{\tau}}{2k_c^2} + \frac{\nabla^2 \tilde{\rho}}{k_c^2} \right]. \quad (35)$$

We call V and $\tilde{V}$ the mean-field and the pairing potentials, respectively.

When there are no pairing correlations, the mean-field Hamiltonian h is identical to the HF single-particle Hamiltonian. Therefore, its expectation value,

$$\epsilon_i = \langle \psi_i | h | \psi_i \rangle, \quad (36)$$

may be called the single-particle energy of the i th canonical orbital. The negative of the expectation value of the pairing Hamiltonian,

$$\Delta_i = -\langle \psi_i | \tilde{h} | \psi_i \rangle, \quad (37)$$

has a meaning of the pairing gap of the orbital. The pairing gap should be positive or zero. Indeed, Δ_i could take negative values only if the wave function would consist of very high-momentum components [22]. A related discussion is given in Sec. VIB.

The quasiparticle states of Eq. (5) are the eigenstates of their own Hamiltonian, i.e., so-called HFB super matrix composed of h and $\tilde{h}$:

$$\begin{pmatrix} h - \epsilon_F & \tilde{h} \\ \tilde{h} & -h + \epsilon_F \end{pmatrix} \begin{pmatrix} \phi_i \\ \varphi_i \end{pmatrix} = E_{\text{qp}}^{(i)} \begin{pmatrix} \phi_i \\ \varphi_i \end{pmatrix}, \quad (38)$$

where ϵ_F is the Fermi level. In small subspaces like several major shells, the easiest way to obtain an HFB solution is to solve Eq. (38) as an eigenvalue problem of a hermitian matrix. In large spaces like mesh representations, however, it is easier to obtain the canonical orbitals directly, rather than via quasiparticle states. Such a direct method is explained in the next section.

Incidentally, if one considers seriously that ψ_i is a real function, one may notice that the functional derivative should be doubled since

$$\frac{\delta E_{\text{tot}}}{\delta \psi_i} = \frac{\delta E_{\text{tot}}}{\delta \psi_i^{\text{bra}}} \frac{\delta \psi_i^{\text{bra}}}{\delta \psi_i} + \frac{\delta E_{\text{tot}}}{\delta \psi_i^{\text{ket}}} \frac{\delta \psi_i^{\text{ket}}}{\delta \psi_i} = 2 \cdot 4\mathcal{H}_i \psi_i, \quad (39)$$

as $\psi_i^{\text{bra}} = \psi_i$ and $\psi_i^{\text{ket}} = \psi_i$. Eq. (39) seems to be a more appropriate expression of what our numerical calculation program actually does. However, the factor 2 at

the beginning of the right-hand side as well as the factor 4 which reflects the spin-isospin degeneracy do not matter because they can be conveniently absorbed into the step-size parameter of the gradient method (see Sec. V).

IV. CUT-OFF SCHEMES FOR THE PAIRING INTERACTION

In this section we discuss on the cut-off schemes for zero-range pairing interactions in relation to the canonical-basis HFB method.

Delta function forces without a cut-off lead to a divergence of the strength of the pairing correlation. In order to prevent the divergence, one usually takes only those quasiparticles whose excitation energy $E_{\text{qp}}^{(i)}$ is lower than some cut-off energy E_c in constructing the ground state [3]. Namely Eq. (4) is modified to

$$|\Psi\rangle = \prod_{i=1}^{N_B} \theta(E_c - E_{\text{qp}}^{(i)}) b_i |0\rangle, \quad (40)$$

where θ is the Heaviside (step) function.

In this paper we do not discuss how one should change the strength as a function of E_c for renormalization. Instead, we regard E_c as one of the constants to define the force.

In order to implement the cut-off, one should pay attention to the following two peculiarities of the canonical-basis HFB method. i) The introduction of E_c causes a serious inconvenience to this method, i.e., the absence of the quasiparticle Hamiltonian. For this reason, it is preferable to use the number of canonical orbitals N_w instead of E_c . ii) For delta-function pairing interactions, substitution of E_c with N_w leads to a physically meaningless situation, in which canonical orbitals are collapsed to a spatial point (a point collapse phenomenon, hereafter). To overcome this difficulty, we modify the pairing interaction by adding a repulsive momentum-dependent term. In the rest of this section we discuss these two problems.

i) Let us explain how the introduction of the cut-off causes the absence of the quasiparticle Hamiltonian. An analogy with the BCS approximation indicates a natural way to introduce an energy cut-off to the canonical-basis method. Namely, the smooth cut-off method[15] modifies the seniority interaction as

$$\hat{v}_{\text{pair}} = -G \left(\sum_{i>0} f_i a_i^\dagger a_i^\dagger \right) \left(\sum_{j>0} f_j a_j a_j \right), \quad (41)$$

where $f_i = f(\epsilon_i)$ is a function of single-particle energy ϵ_i and takes on ~ 1 well below a chosen cut-off energy and smoothly becomes zero above it. The smoothness is indispensable to the stability of the solution. In analogy, we may modify the pairing density as

$$\tilde{\rho} = 4 \sum_{i=1}^{N_w} u_i v_i |\psi_i|^2 \rightarrow 4 \sum_{i=1}^{N_w} f_i u_i v_i |\psi_i|^2 \quad (42)$$

with

$$f_i = \exp\left(-\frac{\mu^2}{4} k_i^2\right), \quad k_i^2 = - \int \psi_i^*(\mathbf{r}) \nabla^2 \psi_i(\mathbf{r}) d^3r. \quad (43)$$

In Eq. (43), we assume a dependence on the kinetic energy ($\propto k_i^2$), not on the mean-field energy ϵ_i as in Eq. (41), to avoid a highly complicated expression of the gradient for the latter case. (In BCS, such complications are simply neglected.) The gradient is given for $k_c = \infty$ by

$$\frac{1}{4} \frac{\delta E_{\text{tot}}}{\delta \psi_i^*} = \left[v_i^2 h + u_i v_i \tilde{h} \{ f(k_i^2) + f'(k_i^2) \nabla^2 \} \right] \psi_i. \quad (44)$$

This method works well to prevent the point collapses in numerical tests using $\mu = 1.2$ fm taken from the Gogny force [23]. However, this cut-off scheme has an disadvantage that the HFB super matrix in Eq. (38) cannot be defined, because in Eq. (44) the pairing Hamiltonian (the part proportional to $u_i v_i$ in square brackets) is dependent on the canonical-orbital index i . This means that there is no common pairing Hamiltonian to all the quasiparticles. Consequently one does not have well-defined Bogoliubov quasiparticle states and cannot utilize them to refine the HFB solution, which is a rather serious drawback as discussed in the next section. If one can use N_w in place of E_c , however, one can recover a unique quasiparticle Hamiltonian.

Incidentally, a similar kind of ambiguity arises from the cut-off scheme in terms of the quasiparticle energies according to Eq. (40). In this case, the canonical orbitals do not have well-defined Hamiltonians. It may not matter, however, because one does not need Hamiltonians to define canonical orbitals when they can be obtained by transforming the quasiparticle states.

ii) Let us discuss the phenomenon of the point collapse. In quasiparticle (or two-basis) HFB method, specifying the number of quasiparticle (HF single-particle) states to be considered has the same consequences as imposing an energy cut-off because the states to be chosen are anyway the eigenstates of the lowest energies of the quasiparticle (HF) Hamiltonian.

On the other hand, the canonical-basis HFB method is very peculiar concerning this point. The canonical orbitals are not the eigenstates of a single operator but each of them has its own Hamiltonian $\mathcal{H}_i$ as a function of the occupation probability given by Eq. (29). $\mathcal{H}_i$ becomes h and $\tilde{h}$ in the two extreme situations $v_i^2=1$ and 0, respectively. It is only when one considers a small number of orbitals that all of them are the lowest-energy approximate eigenstates of h . Otherwise, some of the orbitals may become the eigenstates of $\tilde{h}$ rather than h : We show in Appendix B that, if the occupation probability of an orbital becomes sufficiently small, it spontaneously decreases the probability further toward zero (to decrease the total energy of the nucleus) and change its Hamiltonian to $\tilde{h}$. This occurs when the pairing force is a delta function (with or without particle-density dependence),

for which $\tilde{h}$ is a local potential and thus its eigenstates are delta functions in the spatial coordinate. This means that their $\langle h \rangle$ is infinitely high. On the other hand, the rest of the orbitals are left in low-energy subspace of h . Therefore the restriction on N_w results in utterly different solutions from those obtained by using a cut-off energy explicitly.

This peculiarity of the canonical-basis method is essential to the implementation of the method. In the quasiparticle and the two-basis methods, the unphysical divergence of the pairing correlation strength occur only in the limit of $N_w \rightarrow \infty$ (supposing N_w is used instead of E_c). In the canonical-basis method, in addition to this divergence, a different type of unphysical behavior (the point collapse) can also happen for N_w fixed at finite numbers. One has to take special care of the latter problem if one tries to implement the canonical-basis method.

Now, if one can suppress the point collapse, one is allowed to use N_w as the control parameter of the cut-off energy. Appendix B shows that this can be achieved, e.g., by introducing a sufficiently strong repulsive momentum dependence to the delta-function pairing interaction. With this term applied to finite (small or large) numbers of canonical orbitals, unphysical situations including the point collapse never happen. (If it is applied to infinite number of orbitals, not the point collapse but the divergence occurs [22].) In this paper we employ this momentum-dependent force.

In addition to the role to enable a cut-off in terms of N_w , equally important is the byproduct that it also clarifies the nature of high-lying canonical orbitals by providing a kinetic energy term to the pairing Hamiltonian $\tilde{h}$. Further explanations using a numerical example are given in Sec. VI B.

Incidentally, Appendix B also gives a discussion on an alternative way in terms of a pairing-density dependent force to enable cut-off in terms of N_w .

Before ending this section, we mention the prospect about the renormalization of the pairing force strength. Considering the recent quantitative success of the regularization method of delta-function forces based on the Thomas-Fermi approximation [24, 25, 26, 27], we think it is worth trying in the canonical-basis method in future.

However, it will require a special treatment. The Thomas-Fermi approximation makes the interaction strength a decreasing function of the particle density. One might expect this modification of the interaction would hinder the point collapse. Actually, dependences on particle density cannot prevent it because the collapse makes only the pairing density divergent but leaves the particle density unchanged (because $v \propto w^{3/2}$ and $|\psi_w(0)|^2 \propto w^{-3}$ as shown in Appendix B). Therefore one has to keep the momentum-dependent term. This will lead to a modification of the regularization procedure.

V. GRADIENT METHOD FOR CANONICAL-BASIS HFB

We explain in this section the details of a procedure to obtain the canonical-basis solution of the HFB equation directly, not by way of quasiparticle states. What should be done is to minimize E_{tot} of Eq. (22) under constraints of Eqs. (12) and (13). Equivalently, one may introduce a Routhian,

$$R = E_{\text{tot}} - 4\epsilon_F \sum_{i=1}^{N_w} v_i^2 - 4 \sum_{i=1}^{N_w} \sum_{j=1}^{N_w} \lambda_{ij} \{ \langle \psi_i | \psi_j \rangle - \delta_{ij} \}, \quad (45)$$

and minimize it without constraints. ϵ_F is probably the most familiar Lagrange multiplier, whose physical meaning is the Fermi level. In the definition (45), N_w^2 Lagrange multipliers λ_{ij} obeying hermiticity,

$$\lambda_{ij} = \lambda_{ji}^*, \quad (46)$$

are introduced instead of $\frac{1}{2}N_w(N_w+1)$ independent multipliers. The hermiticity ensures the equality between the number of constraints and the number of independent multipliers. Moreover, it makes R real so that two conditions, $\delta R / \delta \psi_i = 0$ and $\delta R / \delta \psi_i^* = 0$, become equivalent and thus one has to consider only one of them. Note that δ_{ij} is subtracted from $\langle \psi_i | \psi_j \rangle$, in contrast to Ref. [11]. This subtraction is necessary to treat λ_{ij} not as constants like ϵ_F but as functionals of the wave functions.

The stationary condition of R results in two kinds of equations. One is $\partial R / \partial v_i = 0$, which concerns the occupation amplitudes v_i and is fulfilled by [11]

$$v_i^2 = \frac{1}{2} \pm \frac{1}{2} \frac{\epsilon_i - \epsilon_F}{\sqrt{(\epsilon_i - \epsilon_F)^2 + \Delta_i^2}}. \quad (47)$$

Among the double sign, the minus sign corresponds to the minimum. The relative sign between v_i and $u_i = \pm \sqrt{1 - v_i^2}$ should be plus, i.e., $u_i v_i \geq 0$ (unless $\Delta_i < 0$). The stationary condition for a wave function $\psi_i(\mathbf{r})$ leads to the following equation:

$$\frac{1}{4} \frac{\delta R}{\delta \psi_i^*} = \mathcal{H}_i \psi_i - \sum_{j=1}^{N_w} \lambda_{ij} \psi_j - \sum_{j=1}^{N_w} \sum_{k=1}^{N_w} \frac{\delta \lambda_{jk}}{\delta \psi_i^*} \{ \langle \psi_j | \psi_k \rangle - \delta_{jk} \} = 0, \quad (48)$$

Owing to the state dependence of $\mathcal{H}_i$, the orthogonal condition becomes nontrivial to fulfill. In HF, the orthogonality is automatically satisfied because ψ_i are eigenstates of the same hermite operator h , which are orthogonal to one another. The orthogonalization procedure is needed only because of the instability for decaying into Pauli-forbidden configurations. On the other hand,

in the canonical-basis HFB method, the orthogonalization is indispensable and the explicit functional form of λ_{ij} is the most important secret of the method.

Reinhard *et al.* have proposed [11]

$$\lambda_{ij} = \frac{1}{2} \langle \psi_j | (\mathcal{H}_i + \mathcal{H}_j) | \psi_i \rangle. \quad (49)$$

Let us give our reasoning on how the above form can be deduced. This consideration plays the crucial role in order to modify the form for the sake of a faster convergence. The requirement that Eq. (48) must hold at the solution (where $\langle \psi_i | \psi_j \rangle = \delta_{ij}$) means,

$$\mathcal{H}_i | \psi_i \rangle = \sum_{k=1}^{N_w} \lambda_{ik} | \psi_k \rangle \quad (\text{at the solution}). \quad (50)$$

By taking the overlap with $\langle \psi_j |$, one obtains,

$$\lambda_{ij} = \langle \psi_j | \mathcal{H}_i | \psi_i \rangle \quad (\text{at the solution}). \quad (51)$$

Eqs. (49) and (51) are equivalent at the solution because λ_{ij} is defined to be hermite by Eq. (46). However, one should employ Eq. (49) rather than Eq. (51) because the former, but not the latter, is hermite at points other than the solution.

One can utilize the gradient method to obtain the HFB solutions in the canonical-basis formalism. Let us describe this method briefly: Small variations in ψ_i and ψ_i^* change the Routhian as,

$$\delta R = \frac{\delta R}{\delta \psi_i} \delta \psi_i + \frac{\delta R}{\delta \psi_i^*} \delta \psi_i^*, \quad (52)$$

which indicates the steepest descent direction to be,

$$\delta \psi_i \propto -\frac{\delta R}{\delta \psi_i^*}, \quad \delta \psi_i^* \propto -\frac{\delta R}{\delta \psi_i}. \quad (53)$$

One takes a small distance movement toward this direction, i.e., $\psi_i \rightarrow \psi_i + \delta \psi_i$ with

$$\delta \psi_i = -\Delta t \left\{ \mathcal{H}_i \psi_i - \sum_{j=1}^{N_w} \lambda_{ij} \psi_j \right\}. \quad (54)$$

By repeating the evaluation of $\{\delta \psi_i\}$ and the movement, one eventually reaches the minimum of R . Incidentally, in the braces on the right-hand side, the term including $\delta \lambda_{jk} / \delta \psi_i^*$ in the second member of Eqs. (48) is dropped because we know empirically that the orthogonality is stable without this term.

In Eq. (54), Δt is a parameter introduced to control the size of a movement. One should regard that the prefactors on the right-hand side of Eq. (39) are included in this parameter. One may call Δt the imaginary-time-step size because the first order approximation in Δt of the imaginary-time evolution method [29] becomes essentially the same procedure as the gradient method :

$$\begin{aligned} \delta \psi_i &= e^{-\Delta t \mathcal{H}_i} \psi_i - \psi_i \\ &= -\Delta t \mathcal{H}_i \psi_i + \mathcal{O}(\Delta t^2). \end{aligned} \quad (55)$$

In order to justify the negligence of the higher-order terms in Eq. (55), it must hold[28]

$$f_{\text{evo}} < 2 \quad \text{for} \quad \Delta t = \frac{f_{\text{evo}}}{T_{\text{max}}}, \quad (56)$$

where T_{max} is the maximum kinetic energy (used as the upper bound of the single-particle energy). For the Cartesian mesh representation with a mesh spacing a ,

$$T_{\text{max}} = 3 \left(\frac{\pi}{a} \right)^2 B(\rho), \quad (57)$$

where $B(\rho)$ is given by Eq. (32). By choosing ρ between $\rho = 0$ (free space) and $\rho = 0.16 \text{ fm}^{-3}$ (nuclear matter density), one obtains $T_{\text{max}} = 1254 \text{ MeV}$ for the SIII force with $a = 0.8 \text{ fm}^{-1}$. For the calculations shown in this paper, we have used $f_{\text{evo}} = 1.0$, i.e., $\Delta t = 5 \times 10^{-25} \text{ sec}$. Kinetic energy also arises from the pairing Hamiltonian $\tilde{h}$. However, an estimation by replacing $B(\rho)$ of Eq. (57) with $\tilde{B}(\tilde{\rho})$ of Eq. (34) results in an order of magnitude smaller value.

What is presented above may be called a naïve version of the gradient method. The convergence to the HFB solution turns out to be very slow with this naïve method. A numerical example will be given in Sec. VIA. The origin of this slowness can be traced back to the factor $u_i v_i$ in $\mathcal{H}_i$, which is just a linear combination of h and $\tilde{h}$ with coefficients v_i^2 and $u_i v_i$. The effects of $\mathcal{H}_i$ can be very weak for canonical orbitals having small v_i , which leads to the smallness of their changes in a gradient-method step.

Now, steepest-descent paths depend on the choice of the variables. For example, Eq. (54) is obtained when one uses ψ_i as the variables. If one uses norm-resized wave functions $\chi_i = \psi_i / \sqrt{\alpha_i}$, where α_i is a scaling factor, a gradient-method step becomes $\delta \chi_i \propto -\delta R / \delta \chi_i^*$, which is equivalent to

$$\delta \psi_i = -\Delta t \alpha_i \frac{\delta R}{\delta \psi_i^*} = -\alpha_i \Delta t \left(\mathcal{H}_i \psi_i - \sum_j \lambda_{ij} \psi_j \right). \quad (58)$$

Thus the path is changed. By choosing α_i to cancel the small factors in $\mathcal{H}_i$, one can accelerate the otherwise slow convergence, which we call the accelerated gradient method.

In this paper, we take

$$\alpha_i \simeq \min \left(\frac{1}{v_i^2}, \frac{f_{\text{acc}}}{u_i v_i} \right), \quad (59)$$

where the factor f_{acc} may be chosen empirically to maximize the speed of convergence. We choose $f_{\text{acc}} = 5$. This factor seems to take care of the fact that $\tilde{h}$ is smaller than h by an order of magnitude. With this choice for the scaling factor, $\alpha_i \mathcal{H}_i \sim h$ for deeply bound orbitals and $\alpha_i \mathcal{H}_i \sim 5\tilde{h}$ for high-lying orbitals. Thus, all the orbitals evolve at roughly the same pace.

Incidentally, by using the approximate equality symbol in Eq. (59), we mean the utilization of some common recipes for numerical calculations like taking a moving average and restricting on the maximum values.

It should be noticed here that one should also modify the form of multipliers λ_{ij} when one introduces the acceleration factors $\alpha_i \neq 1$. In principle one may reach the solution by using Eq. (49) because transformations of variables do not change the location of the minimum of R . Nevertheless, one should modify Eq. (49) for a practical reason. In calculating the gradient vector whose exact form is given by the second member of Eqs. (48), the last term takes much more computing time than the first two terms due to $\delta\lambda_{jk}/\delta\psi_i^*$. One can drop the last term if the orthogonality relation (12) is fulfilled along the path of the evolution. Let's suppose that the relation is satisfied before a gradient-method step is taken and require that it is conserved without the dropped term to the first order in Δt after the step, i.e.,

$$\langle\psi_i|\psi_j\rangle = \delta_{ij}, \quad \langle\psi'_i|\psi'_j\rangle = \delta_{ij} + \mathcal{O}\left((\Delta t)^2\right), \quad (60)$$

with $\psi'_i = \psi_i + \delta\psi_i$ and $\delta\psi_i$ given by Eq. (58). Substituting ψ_i and ψ'_i in Eq. (60) and requiring the hermiticity (46) result in

$$\lambda_{ij} = \frac{1}{\alpha_i + \alpha_j} \langle\psi_j|(\alpha_i\mathcal{H}_i + \alpha_j\mathcal{H}_j)|\psi_i\rangle. \quad (61)$$

This new form of λ_{ij} , as well as the original form of Eq. (49), fulfills the requirement that it should agree with the expression (51) at the solution. The original form differs from the new form, however, before reaching the solution if $\alpha_i \neq \alpha_j$. Consequently, only the new form conserves the orthogonality during the course of the evolution.

We have indeed suffered from large errors of orthogonality by using the original form. On the other hand, by using the new form, we have observed that the error does not grow but decreases without performing explicit orthogonalizations. The reason for this stability will probably be found in the second order terms in Δt neglected in Eq. (60).

There is an auxiliary method to speedup the convergence. It is to diagonalize the HFB super matrix given by Eq. (38) in the subspace spanned by N_w canonical orbitals. Then one obtains N_w quasiparticle states with positive energy, whose two-component wave functions defined in Eq. (5) are expressed as,

$$\phi_i(\mathbf{r}) = \sum_{j=1}^{N_w} \psi_j(\mathbf{r}) U_{ji}, \quad \varphi_i(\mathbf{r}) = \sum_{j=1}^{N_w} \psi_j(\mathbf{r}) V_{ji}, \quad (62)$$

where $(U_{1i}, \dots, U_{N_w i}, V_{1i}, \dots, V_{N_w i})^T$ is the i th normalized eigenvector of Eq. (38). The HFB ground state is constructed as the vacuum of these quasiparticles as in Eq. (4). By diagonalizing the one-body density matrix of this vacuum in this subspace, V^*V^T , one obtains a

renewed set of canonical orbitals as the eigenvectors and v_i^2 as the eigenvalues. If the initial set of canonical orbitals are taken from the exact solution, the renewed and the initial sets are identical. However, if the initial set is taken before the state converges to the solution, the renewed set corresponds to a better solution than the initial set. It is because the above procedure gives the exact variational minimum [21, 30] in the subspace spanned by the initial canonical orbitals. The gradient-step method takes care of both the variation inside this subspace and the optimization of the subspace itself. The diagonalization performs only the former part but perfectly in a single step. This diagonalization method is not indispensable but useful to obtain the solutions. It makes the convergence more robust and somewhat quicker if it is performed after every ~ 100 gradient-method steps. Its effect seems to saturate with this interval since using shorter periods does not lead to noticeable improvements. A numerical example is given in Sec. VIA.

Incidentally, the idea of this diagonalization method originates in the two-basis formalism of HFB [5], in which the quasiparticle Hamiltonian is diagonalized in the subspace spanned by low-lying HF orbitals (eigenstates of h), not the canonical orbitals as in this paper.

The relation between these quasiparticles and the true quasiparticles defined in the full space is discussed in Sec. VID.

VI. RESULTS OF NUMERICAL CALCULATIONS

In this section, we show the results of numerical calculations using a newly developed computer program [8, 12, 13, 14] of the canonical-basis HFB method in a three-dimensional Cartesian mesh representation. The parameters of the model are as follows: For the mean-field interaction, Skyrme SIII force is employed but its spin-orbit term and the Coulomb force are not included. For the pairing interaction, $\rho_c = 0.32 \text{ fm}^{-3}$ and $\tilde{\rho}_c = \infty$ are used. The value of v_p is changed depending on $k_c (= 1.7 - 5 \text{ fm}^{-1})$ and $N_w (= 14 - 210)$ to make the average pairing gap to be 2 - 2.5 MeV. Unless the values are specified, $k_c = 2 \text{ fm}^{-1}$, $v_p = -1050 \text{ MeV fm}^3$, and $N_w = 21$ are used. With $N_w = 21$, the number of orbitals amounts to three times as large as the number of the nucleons, since each orbital can be occupied by four nucleons due to the spin-isospin degeneracy.

The calculated state is the axially symmetric prolate solution of $^{28}\text{Si}_{14}$. The single-particle wave functions are expressed on a Cartesian mesh having (in the default set up) $29 \times 29 \times 29$ mesh points with mesh spacing $a = 0.8 \text{ fm}$. As the boundary condition, we assume a cubic box whose infinitely high walls are located at the 0th and the 30th mesh points. The center of mass of the nucleus is placed at the center of the box. The 17-point formulae [31] are employed to calculate the first and second derivatives. In applying these formulae, wave functions

are assumed to be antisymmetrically extended beyond the walls. Spatial integrals are done using the mid-point (=trapezoidal) rule.

A. Convergence to HFB solutions

In Fig. 2, examples of the convergence curves are shown for several versions of the gradient method. The calculations are done using the default parameters. The initial wave functions of the canonical orbitals are taken from the eigenstates of the standard harmonic oscillator potential with a quadrupole deformation of $\beta = 0.3$ and $\gamma = 15^\circ$. The D_{2h} symmetry is conserved to a very good accuracy during the course of the gradient-method evolutions.

For the size of an imaginary time step, we use $f_{\text{evo}} = 1.0$, defined by Eq. (56), for all the curves. This value of f_{evo} roughly optimizes the convergence speed for the fastest method. For slower methods, f_{evo} may be slightly larger but such a small change does not affect our discussions below.

In connection with the step size, we also adopt a recipe from the HF+BCS method of Ref. [15], according to which the changes of h and $\tilde{h}$ after each gradient-method step should be further damped compared with the changes of ψ_i (by a factor of 0.4 in our case). It is a precaution against occasional instabilities like oscillating behaviors. This additional damping does not affect our conclusion on the comparison of the methods, either.

The top portion of Fig. 2 shows the total energy E_{tot} of Eq. (22). The middle portion shows the maximum over $i = 1, \dots, N_w$ of the error of the second equality of Eqs. (48) (neglecting the contribution from the error of orthogonality),

$$\Delta\epsilon_i^{\text{HFB}} = \left| \mathcal{H}_i \psi_i - \sum_{j=1}^{N_w} \lambda_{ij} \psi_j \right|, \quad (63)$$

which is an indicator of the accuracy of HFB solutions. As for HF, this quantity is reduced to the maximum over $i = 1, \dots, \frac{1}{4}A$ of

$$\Delta\epsilon_i^{\text{HF}} = |h\psi_i - \epsilon_i\psi_i| = \sqrt{\langle\psi_i|h^2|\psi_i\rangle - \langle\psi_i|h|\psi_i\rangle^2}, \quad (64)$$

which is just the energy width of $|\psi_i\rangle$ for h . The bottom portion shows the mass quadrupole deformation parameter β defined as the general definition [21] times $\sqrt{45/16\pi} \simeq 0.95$ disregarding nucleon form factors. HF result for β , converging to 0.44, is omitted. The abscissae are common to all the portions and designate the number of gradient-method steps.

Thin solid lines in all the three portions are the result of the naïve (i.e., with $\alpha_i = 1$) gradient method. These curves demonstrate that one can indeed obtain an HFB solution with the canonical-basis HFB method on a mesh, because after a million steps, E_{tot} and β appear to reach a plateau and $\Delta\epsilon_i^{\text{HFB}}$ becomes as small as 0.1 keV. We have also obtained similar convergence curves

FIG. 2: Convergence to HF and HFB solutions for ^{28}Si . See text for explanations.

for other quantities like the axial asymmetry γ and the r.m.s. radius. There is a serious problem, however, of the obvious slowness of the convergence.

Dot curves show the convergence to an HF solution with pairing interactions turned off. (With “w/D” in the legend in the top portion of the figure we mean that diagonalization of h is done in the subspace of occupied $\frac{1}{4}A = 7$ HF orbitals to renew the orbitals after every 100 gradient-method steps. Without this diagonalization, ψ_i are not HF orbitals and do not satisfy $\Delta\epsilon_i^{\text{HF}} = 0$. This diagonalization also makes the convergence somewhat quicker.) One can see that the HF energy reaches a plateau by three orders of magnitude faster than the naïve HFB method. In the middle portion, while HF can achieve precision of 0.1 keV with only 1400 steps, HFB requires 55000 steps for 10 keV, 3×10^5 steps for 1 keV, and 1.5×10^6 steps for 0.1 keV precisions.

A method to improve the convergence speed is the diagonalization of the HFB super matrix in the subspace spanned by N_w canonical orbitals. Dot-dash curves are

obtained by performing this diagonalization after every 100 steps. One can see that the convergence speed is improved by an order of magnitude. However, this progress is not satisfactory yet compared with the HF curve.

Dash curves uses the accelerated gradient method (i.e., $\alpha_i \neq 1$, expressed as “w/A” in the legend), which brings about a speedup by two orders of magnitude. A comparison with dot-dash curves suggests that the variation of the canonical-basis subspace itself is a more important factor than a minimization inside the subspace.

Using both the diagonalization and the acceleration methods leads to thick solid curves (expressed as “w/A,D” in the legend). Steep changes in every 100 steps are due to the diagonalizations. One can see that these curves converge almost as quickly as the dot curves of the HF method. These results demonstrate that canonical-basis HFB can be solved without very heavy numerical computations by adopting the two improvements described above.

B. Properties of the canonical-basis orbitals

In this subsection, we use Fig. 3 to discuss the properties of the canonical orbitals in connection with the mean-field and the pairing Hamiltonians. An analysis using these two Hamiltonians leads to a comprehensive understanding of the nature of high- as well as low-lying canonical orbitals. The calculation has been done for ^{28}Si with $N_w = 210$ canonical orbitals, which is 30 times as many as the number of the orbitals below the Fermi level. For the combination of this N_w and $k_c = 2 \text{ fm}^{-1}$, we have adjusted the strength of the pairing force to be $v_p = -837 \text{ MeV}$ so that the average pairing gap have a reasonable size, 2.0 MeV.

The result shown in Fig. 3 has been obtained after 1.2×10^5 gradient-method steps: Because of the slow convergence of very high-lying orbitals (even using the accelerated method), we continued the gradient-method evolution until no changes are going on in any of ϵ_i . The last change took place during 5×10^4 th to 8×10^4 th steps, in which two orbitals gradually increased their energies from $\sim 50 \text{ MeV}$ to $\sim 80 \text{ MeV}$. During this change $\Delta\epsilon_i^{\text{HFB}}$ increased slightly up to $3 \times 10^{-5} \text{ MeV}$. In the last 4×10^4 steps there were no changes and $\Delta\epsilon_i^{\text{HFB}}$ was decreased to $< 10^{-5} \text{ MeV}$.

The top-left panel shows the logarithm of the occupation probability v_i^2 . The abscissa (common to all the four panels in the left column) is the label i of canonical orbitals, which are sorted in the descending order of v_i^2 . First seven orbitals have occupation probabilities close to unity. Above them, the decrease of the probability looks rather steady. It is in fact a result of a mixing of several sequences: The top-right panel plots the same v_i^2 data versus ϵ_i (only $\epsilon_i > 0$ part is shown), in which one can see three sequences. Let us denote the number of the oscillator quanta by N_{osc} . We have confirmed that the top sequence corresponds to $N_{\text{osc}} = l$ subshells ($4 \leq l \leq 9$

are completely seen in $\epsilon > 0$ region). The lower bunch of dots are for $l \leq N_{\text{osc}} - 2$. For $\epsilon > 40 \text{ MeV}$, $l = N_{\text{osc}} - 2$ sequence is bifurcated from $l \leq N_{\text{osc}} - 4$ sequences. These observations indicate that the canonical orbitals have the same shell structure as that of the harmonic oscillator at least up to several tens of MeV. Then, a question arises what generates this shell structure. The second and third top portions give clues to answer this question.

The panels in the second top row show the mean-field Hamiltonian h and its expectation value and width for each canonical orbital. In the right panel, the mass term B and the potential term V of h are plotted as functions of the distance from the center of the nucleus. Their profiles in the symmetry (z) axis as well as those in the equatorial (xy) plane are shown. In the left panel, mean-field energy of each canonical orbital is designated using a dot and a vertical line. The dot corresponds to the expectation value ϵ_i while the vertical line connects between $\epsilon_i \pm \Delta\epsilon_i$ with

$$\epsilon_i = \langle \psi_i | h | \psi_i \rangle, \quad \Delta\epsilon_i = \sqrt{\langle \psi_i | h^2 | \psi_i \rangle - \epsilon_i^2}. \quad (65)$$

One can see that first seven orbitals, which are below the Fermi level, have very narrow widths (30 – 760 keV): They are approximate eigenstates of h , i.e., the (occupied) HF orbitals. Above the Fermi level, the width becomes larger with increasing expectation value and thus the wave functions of canonical orbitals begin to diverge from those of (unoccupied) HF orbitals. At the crossing point from negative to positive ϵ_i , there seems to be only a smooth continuation of this trend. This is an essential difference between the HFB canonical and the HF orbitals. Concerning the HF orbitals, ϵ_i may be estimated in the Thomas-Fermi approximation, where the number of levels of h below ϵ is given as,

$$\Gamma(\epsilon) = \frac{1}{6\pi^2} \int \left\{ \frac{\epsilon - V(\mathbf{r})}{B(\mathbf{r})} \right\}^{3/2} \theta(\epsilon - V(\mathbf{r})) d^3r. \quad (66)$$

The widths of HF orbitals are always zero. The solid curve designates the function $i = \Gamma(\epsilon)$. It is owing to the finite volume of the normalization box that $\Gamma(\epsilon)$ is not infinite for positive ϵ . One can see a distinct difference between this curve for the HF orbitals and the dots for the HFB canonical orbitals: The level density is by far sparser in the latter. (It is indeed the reason to use canonical orbitals as discussed in Sec. II.) It seems difficult to relate the level structure of canonical orbitals to h .

Incidentally, one can see a bifurcation of the sequence of the dots (i, ϵ_i) at $i \sim 30$. Its origin is the subshell structure: Upper sequence corresponds to high-angular momentum ($l = N_{\text{osc}}$) subshells while the lower one to $l \leq N_{\text{osc}} - 2$ subshells.

The third panels from the top show similar graphs to the second top panels but for the pairing Hamiltonian $\tilde{h}$. In the right panel, attention should be paid to the scale of the ordinate, which is smaller by an order of magnitude

FIG. 3: Relations between the properties of canonical-basis orbitals and the mean-field and pairing Hamiltonians for ^{28}Si . Panels in the left column show occupation probability, mean-field energy, pairing energy, and radial density distribution for each canonical-basis orbital. Panels in the right column show the occupation probability (again, but versus the mean-field energy), mass and potential terms of the mean-field Hamiltonian, those of pairing Hamiltonian, and the density distribution of the nucleus. See text for explanations.

than that for h . It is because the expectation value of $\tilde{h}$ is nothing but the negative pairing gap (i.e., $\tilde{\epsilon}_i = -\Delta_i$) and thus its size is only a few MeV. In the left panel, dots are plotted at $\tilde{\epsilon}_i$ and vertical lines connect between $\tilde{\epsilon}_i \pm \Delta\tilde{\epsilon}_i$, where

$$\tilde{\epsilon}_i = \langle \psi_i | \tilde{h} | \psi_i \rangle, \quad \Delta\tilde{\epsilon}_i = \sqrt{\langle \psi_i | \tilde{h}^2 | \psi_i \rangle - \tilde{\epsilon}_i^2}. \quad (67)$$

One can see an opposite trend of the width between h and $\tilde{h}$: In the former (latter), the width is smaller for lower (higher) expectation values. It suggests a view that high-lying canonical orbitals are closely related to $\tilde{h}$. This can be understood in terms of the state dependent Hamiltonian, $\mathcal{H}_i = v_i^2 h + u_i v_i \tilde{h}$. Because of this form, it is close to h ($\tilde{h}$) for deeply bound (highly excited) canonical orbitals.

The solid curve designates the Thomas-Fermi estimation of $\tilde{\Gamma}(\tilde{\epsilon})$, the number of levels of $\tilde{h}$ below $\tilde{\epsilon}$. $\tilde{\Gamma}$ can be obtained by replacing Γ, ϵ, V, B with $\tilde{\Gamma}, \tilde{\epsilon}, \tilde{V}, \tilde{B}$, respectively, in Eq. (66). One can see that this curve agrees quite well with the dots. (Sorting the orbitals more appropriately in the ascending order of $\tilde{\epsilon}_i$ makes the agreement better.) It supports the view that $\tilde{h}$ roughly determines the level structure of canonical orbitals. It also guarantees that the application of the Thomas-Fermi approximation to $\tilde{h}$ provides a rather precise method to count the number of canonical orbitals.

One can see another difference between h and $\tilde{h}$ that ϵ_i becomes positive for $i > 15$ while $\tilde{\epsilon}_i$ is still negative at $i = 210$. It means that $\tilde{h}$ has by far more number of bound states than h . Its origins in the Thomas-Fermi approximation are the larger ratio $\tilde{V}/\tilde{B}$ than V/B inside the nucleus and the vanishing behavior of $\tilde{B}$ as $r \rightarrow \infty$.

It is an interesting question whether there are finite or infinite number of canonical orbitals with $v_i^2 > 0$. Non-zero occupation probability means $\Delta_i > 0$ and thus $\tilde{\epsilon}_i < 0$. Therefore one has to count the number of orbitals with negative $\tilde{\epsilon}$. To give a Thomas-Fermi estimation of this number, let us suppose the form of density tails to be,

$$\tilde{\rho} = \tilde{\rho}_{\text{in}} \frac{e^{-\kappa r}}{\kappa r}, \quad \tilde{\tau} = \tilde{\tau}_{\text{in}} \frac{e^{-\kappa r}}{\kappa r}. \quad (68)$$

For the kinetic-energy density inside the nucleus, a reasonable estimation is $\tilde{\tau}_{\text{in}} = k_F^2 \tilde{\rho}_{\text{in}}$, where $\hbar k_F$ is the Fermi momentum. Using a relation $\nabla^2 \tilde{\rho} = \kappa^2 \tilde{\rho}$ and assuming $\rho \ll \rho_c$ appropriate in the peripheral region, one can show that $\tilde{V}(r)/\tilde{B}(r)$ is independent of r . Consequently, the number of orbitals becomes proportional to the volume of the integral region V_{box} . The explicit form of the result is

$$\Gamma(\tilde{\epsilon} = 0) = V_{\text{box}} \Gamma_0, \quad \Gamma_0 = \frac{1}{6\pi^2} (2k_c^2 - 2\kappa^2 - k_F^2). \quad (69)$$

Therefore, the number of non-zero-occupation canonical orbitals is infinite.

The bottom panels show the radial distributions of the nucleon density (right panel) and that of each canonical

orbital (left panel). The former is shown in two directions while the latter is integrated over the angles as,

$$\rho_i(r) = r^2 \int |\psi_i(\mathbf{r})| d\hat{r}, \quad (70)$$

and thus normalized as $\int_0^\infty \rho_i(r) dr = 1$. Vertical lines are drawn in the interval of r where $\rho_i(r) > 0.001 \text{ fm}^{-1}$. The width of the lines are proportional to $\rho_i(r)$, except that the width is saturated at 0.8 (in the scale of the abscissa) for $\rho_i(r) \geq 0.5 \text{ fm}^{-1}$. One can see that the canonical orbitals are localized in the neighborhood of the nucleus and only gradually shifted outward with increasing i . It is not due to the finite box size because even the 210th orbital is located far from the boundary, which is at 12 to $12\sqrt{3} \text{ fm}$. The location of the maximum of $\rho_i(r)$ agrees fairly well with the classical turning point of $\tilde{V}$ for energy $\tilde{\epsilon}_i$ (as seen in the third top panel in the right column). This vindicates the view that $\tilde{h}$ determines the spatial extent of high-lying canonical orbitals.

Let us give another fact to confirm this view. Evaluating Eq.(69) using $k_c = 2 \text{ fm}^{-1}$, $\kappa = 1 \text{ fm}^{-1}$ (see next subsection), and $k_F = 1.4 \text{ fm}^{-1}$, one obtains $\Gamma_0 = 0.14 \text{ fm}^{-3}$. For $\Gamma(\tilde{\epsilon} = 0) = N_w = 210$, the value of V_{box} becomes equal to the volume of a sphere of radius 7.1 fm . This roughly agrees with the fact that the 210th orbital has the maximum density at $r = 7.5 \text{ fm}$.

The discussions of this subsection can be summarized into three points: i) Canonical orbitals well below the Fermi level are localized by the mean-field potential. ii) Highly excited canonical orbitals are localized by the pairing potential. iii) The pairing Hamiltonian can have infinite number of localized orbitals due to the vanishing mass term at large radii.

It should be noted here that we do not insist that $\tilde{h}$ alone determines high-lying orbitals to the details. One has to keep in mind an asymmetry between low- and high-lying orbitals. Because lower-lying orbitals have much stronger influences on the total energy of the nucleus, the determinations of their wave functions are hardly affected by the orthogonality conditions with the higher-lying orbitals. However, the opposite is not true: High-lying orbitals must be orthogonal to the orbitals below the Fermi level, which are determined mainly by h . Consequently, although the most essential points can be explained by the idea of the change of the Hamiltonian from h to $\tilde{h}$, there may still remain something delicate in the treatments of high-lying canonical orbitals compared with those of low-lying ones.

C. Tails of canonical-basis wave functions

Wave functions of bound states have an asymptotic form for large radii of

$$|\psi_i(\mathbf{r})| \sim \frac{e^{-\kappa_i r}}{r}. \quad (71)$$

FIG. 4: Radial density profiles of canonical orbitals of ^{28}Si . The thick line represents the total nucleon density (ρ) while the i th thin line from the top designates the angle-averaged squared wave function of the i th canonical orbital ($|\psi_i|^2$). The canonical orbitals are labeled from 1 to $N_w=21$ in the descending order of v_i^2 . The scale in the ordinate applies only to ρ and $|\psi_1|^2$. The other thin lines are shifted downward so that they do not overlap with each other.

In HF, negative energy orbitals have the form (71) with κ_i determined by ϵ_i as $\hbar\kappa_i = \sqrt{-2m\epsilon_i}$. In HFB, the hole component of quasiparticle wave functions (φ) has this form with κ determined by the excitation energy E_{qp} as $\hbar\kappa = \sqrt{2m(E_{\text{qp}} - \epsilon_F)}$ [3, 4].

As for the canonical orbitals of HFB, however, one cannot relate κ_i to any sort of energies in a simple manner due to the complex influences of the requirement of orthogonality, which is rooted in the lack of a common Hamiltonian to all the orbitals. The only possible statement is that it is not larger than the smallest value of κ for quasiparticles, whose lower bound is given by the Fermi level as in Eq. (14).

In this subsection, we compute κ_i of canonical orbitals numerically using angle-averaged density: $|\psi_i(r)|^2 = \frac{1}{4\pi} \int |\psi_i(\mathbf{r})|^2 d\hat{r}$. In order to see the behaviors at large radii, we have used a large box containing $57 \times 57 \times 57$ mesh points. The edge of the box is $58a=46.4$ fm. The nearest walls from the center of the nucleus is at a distance of 23.2 fm and the farthest (i.e., the corners) at 40.2 fm. For the sake of using the large box, we restrict the number of orbitals to $N_w = 21$, for which an adequate strength of the pairing interaction is $v_p = -1050$ MeV.

Figure 4 shows $|\psi_i(r)|^2$ of canonical orbitals, all of

FIG. 5: Coefficient κ_i for the tails of canonical-orbital wave functions versus the expectation values of the mean-field Hamiltonian ϵ_i . The orbitals are the same as those shown in Fig. 4. Open circles and crosses are for κ at $r = 6$ fm and $r = 20$ fm, respectively.

which have exponentially damping tails. This result demonstrates that the canonical-basis HFB method can convert Gaussian tails of initial wave functions, for which we use eigenstates of a harmonic oscillator, into the correct exponential form.

It is evident that the first orbital changes its slope at around $r = 10.5$ fm. By looking at the other curves minutely, one can also find such changes in several other orbitals. Therefore, we give two discussions, first on the behaviors near the nucleus and second on those far away.

Figure 5 shows κ_i as a function of ϵ_i . Open circles denote κ_i determined by the logarithmic derivative of $r|\psi_i(r)|$ near the nucleus ($r = 6$ fm). One can see less than 21 circles because several pairs of circles overlap exactly due to the degeneracy for the sign of l_z (z -component of the orbital angular momentum). The dash and dot curves represent functions $\hbar\kappa_i = \sqrt{-2m\epsilon_i}$, and $\hbar\kappa_i = \sqrt{2m(\epsilon_i - 2\epsilon_F)}$, respectively. The open circles seem to agree fairly well with a function

$$\hbar\kappa_i = \sqrt{2m(|\epsilon_i - \epsilon_F| - \epsilon_F)}, \quad (72)$$

which coincides with the dash curve for $\epsilon_i < \epsilon_F$ and the dot curve for $\epsilon_i > \epsilon_F$.

By noting that the dash curve expresses κ for bound HF orbitals, one may understand the $\epsilon_i < \epsilon_F$ part of Eq. (72) as indicating that canonical orbitals below the Fermi level have approximately the same tails as HF orbitals.

An alternative interpretation is also possible which refers to the full domain of Eq. (72): Canonical orbitals with $\epsilon_i = \epsilon_F \pm E_{\text{qp}}$ have the same κ as the hole component φ of a quasiparticle state with $E_{\text{qp}} > 0$. It may suggest that canonical orbitals below (above) the Fermi level are related to the hole components of hole-like (particle-like) quasiparticle excitations. However, in order to confirm it, we need quasiparticle states in the full space, which are outside the scope of this paper.

Cross symbols plotted in Fig. 5 are κ_i calculated at a farther radius ($r = 20$ fm). In this case, concerning the deepest and highest orbitals, κ drops toward the minimum value at $\epsilon_i = \epsilon_F$. This may be ascribed to the

fact that the canonical orbitals are constructed by mixing up the hole part of all the quasiparticle states and thus the component having smallest κ dominates in all the canonical orbitals at large radii. Probably, all the canonical orbitals have the same κ ($= \sqrt{2m(E_{\text{qp,min}} - \epsilon_F)/\hbar}$ where $E_{\text{qp,min}}$ is the smallest quasiparticle energy) at sufficiently large radii.

D. Quasiparticle states

Let us discuss on the quasiparticle states defined by Eq. (38) in the subspace spanned by N_w canonical orbitals. These quasiparticles and the true quasiparticles defined in the full space are quite different. The former are only a set of tools for the minimization in a small subspace, while the latter have physical information on the excitation modes of the nucleus.

The width $\Delta E_{\text{qp}}^{(i)}$ (in the full space) of the excitation energy $E_{\text{qp}}^{(i)}$ of the i th quasiparticle (in the subspace) is given by

$$\left(\Delta E_{\text{qp}}^{(i)}\right)^2 = \int (|\phi'_i(\mathbf{r})|^2 + |\varphi'_i(\mathbf{r})|^2) d^3r - \left(E_{\text{qp}}^{(i)}\right)^2, \quad (73)$$

$$\begin{pmatrix} \phi'_i \\ \varphi'_i \end{pmatrix} = \begin{pmatrix} h - \epsilon_F & \tilde{h} \\ \tilde{h} & -h + \epsilon_F \end{pmatrix} \begin{pmatrix} \phi_i \\ \varphi_i \end{pmatrix},$$

where the operation of h and $\tilde{h}$ should be evaluated in the full space (i.e., in the mesh representation), not in the N_w -dimensional subspace.

Quasiparticles can be characterized by the norms of the particle and hole components as well as by the excitation energy. These norms are defined as

$$U_i^2 = \int |\phi_i(\mathbf{r})|^2 d^3r, \quad V_i^2 = \int |\varphi_i(\mathbf{r})|^2 d^3r, \quad (74)$$

for the particle and hole components, respectively. They are normalized as $U_i^2 + V_i^2 = 1$ according to Eq. (6). Quasiparticle states are called to be particle-like (hole-like) if U_i^2 (V_i^2) $> \frac{1}{2}$.

Figure 6 shows E_{qp} and ΔE_{qp} for $N_w = 210$ (with $v_p = -837 \text{ MeV fm}^3$). One can see that hole-like quasiparticles have very small widths. Even the deepest hole state (1s) has a relatively small width (1.7 MeV). On the other hand, the widths of particle-like quasiparticles amount to a few tens of MeV: They are very different from the true quasiparticles defined in the full space.

For the sake of comparison, quasiparticle levels obtained in a smaller subspace ($N_w = 21$, $v_p = -1050 \text{ MeV fm}^3$) are also shown in the top-right window. By comparing the results of two calculations, one can see that increasing the number of canonical orbitals leads to the addition of high-excitation particle-like quasiparticles, while it does not change very much the hole-like

FIG. 6: Excitation energies E_{qp} (dots) and their widths ΔE_{qp} (half of the length of vertical bars) of quasiparticle states of ^{28}Si plotted versus the norm of the hole component. Calculations are done using the HFB solution for $N_w=210$ shown in Fig. 3. The top-right window shows the result for $N_w=21$ for comparison.

states and low-excitation particle-like states. Thus, enlargement of the canonical-basis subspace is a very inefficient way to decrease the energy widths of particle-like quasiparticle states.

The differences from true quasiparticles become more evident by looking at the wave functions. For $E_{\text{qp}} > -\lambda$, the particle component ϕ should be an oscillating function of r [3]. However, ϕ of quasiparticles defined in the canonical-orbital subspace has an exponentially damping tail. It is only natural because they are expressed as linear combinations of such functions.

It should be stressed again that the quasiparticles in the canonical-orbital subspace are nevertheless a useful auxiliary tool to obtain the HFB ground state. However, if one needs true quasiparticle excitation modes, the quasiparticles in the subspace are useless. One has to calculate with some other method the true eigenstates of the quasiparticle Hamiltonian. A good news is that the Hamiltonian (being composed of h and $\tilde{h}$) is already obtained and thus iterations for self-consistency are not necessary. This will make the numerical calculations rather inexpensive.

E. Choice of the value of k_c

Our canonical-basis HFB method has several parameters to specify the pairing force, i.e., the over-all strength v_p , the parameter for the momentum dependence k_c , the number of canonical orbitals having non-zero occupation probabilities N_w , and parameters for density dependences. However, available experimental data do not provide sufficient information on the pairing correlation for precise determinations of so many parameters. Therefore we tune only v_p precisely so that the resulting pairing gap has a desired value, while assuming some reasonable values for the other parameters. However, this does not guarantee that their values may be chosen completely arbitrarily. In this and next subsections we discuss on the

FIG. 7: Dependence of the average pairing gap Δ on the number of canonical orbitals N_w for three sets of pairing interaction parameters k_c (fm^{-1}) and v_p (MeV fm^3). See text for explanations.

choices of the values of k_c and N_w , respectively.

Pairing-channel interactions were taken into account when Skyrme forces SGII [32] and SkP [3] were determined. Their values of k_c ($= \sqrt{-t_0(1-x_0)/t_1(1-x_1)}$) are 2.5 fm^{-1} and 4.3 fm^{-1} , respectively. From this result, values from 2 to 5 fm^{-1} seem equally reasonable.

From a pragmatic point of view to use the force in the canonical-basis method, k_c must be smaller than 6 fm^{-1} in order to avoid the point collapse (see Appendix B). Values smaller than 1.5 fm^{-1} are not preferable, either, because such small k_c makes the solutions very difficult to obtain.

If v_p is adjusted for each value of k_c to reproduce the same value of the average pairing gap, which we define [13] as ,

$$\Delta = \frac{\sum_{i=1}^{N_w} u_i v_i \Delta_i}{\sum_{i=1}^{N_w} u_i v_i}, \quad (75)$$

resulting properties of the nucleus are almost independent of k_c except the pairing density, which becomes more diffuse when smaller k_c is used. Unfortunately, pairing density is rather difficult to determine experimentally.

Incidentally, the properties of each canonical orbital are rather sensitive to k_c : v_i^2 and $\langle r_i^2 \rangle$ increase while ϵ_i decreases with decreasing k_c . Only Δ_i stays roughly constant. Nevertheless, properties of the nucleus (except the pairing density profile) are hardly changed, as far as the average pairing gap is kept unchanged.

From the allowed interval $1.5 \text{ fm}^{-1} \leq k_c \leq 6 \text{ fm}^{-1}$, we have chosen 2 fm^{-1} in this paper. There is no physical reason for this choice. However, smaller values of k_c lead to a favorable situation that the dependence on N_w becomes weaker and the determination of N_w can be less precise. Fig. 7 shows the dependence of Δ of Eq. (75) on N_w . Solid circles, open circles, and triangles are obtained with $k_c = 5, 3$, and 1.7 fm^{-1} , respectively. The values of v_p are given in the legends of the figure in units of MeV fm^3 . Here, v_p is not changed as a function of N_w but is determined for each k_c such that the resulting Δ is

FIG. 8: Pairing force strength v_p adjusted to give $\Delta = 2.5 \text{ MeV}$ as a function of the number of canonical orbitals N_w for ^{28}Si . Dots denote the strengths obtained by the adjustment while the curve represents a function fitted to the dots.

FIG. 9: Dependence of the total energy E_{tot} on the number of canonical orbitals N_w for ^{28}Si . See text for explanations.

roughly the same at $N_w \sim 28$. One can see in the figure that, for $k_c = 1.7 \text{ fm}^{-1}$, $d\Delta/dN_w$ is almost zero around $N \sim 80$. The emergence of this plateau is explained by the vanishing of the pairing interaction at relative momentum k_c . For much larger N_w , Δ will increase again infinitely [22].

F. Dependences on N_w

We next study the dependence on the number of canonical orbitals N_w . Here we adjust the strength v_p for each value of N_w to keep Δ constant. The used values of v_p are shown in Fig. 8.

In Fig. 9 we show the total energy of ^{28}Si as a function of N_w . It is obtained as follows: Starting from harmonic oscillator eigenstates, we obtain an HFB solution for $N_w = 70$. Then, we remove the canonical orbital with the smallest v_i^2 and again obtain the HFB solution for $N_w = 69$ by the gradient method. By repeating this procedure, we obtain solutions for $N_w \geq 14$. This figure shows that the magnitude of the influence of N_w on the total energy is 300 keV or less when v_p is determined for the average pairing gap. Other bulk properties of the nucleus are also roughly independent of N_w : Deformation

FIG. 10: Dependence of the mean-field energies ϵ_i of the canonical orbitals on the number of the orbitals N_w for ^{28}Si . See text for explanations.

parameters β and γ are within 0.374 ± 0.01 and $\pm 0.3^\circ$, respectively. R.m.s mass radius is 3.201 ± 0.004 fm.

Such insensitivity can also be seen in the properties of individual canonical orbitals. In Fig. 10, mean-field energies ϵ_i of canonical orbitals are plotted versus N_w . One can see that ϵ_i below 5 MeV stays almost constant. Higher levels are not so constant but only slightly decreasing. We have also confirmed that other quantities also remain roughly constant.

Therefore, unlike k_c , the effects of changing N_w is almost canceled by the adjustment of v_p .

G. Application to heavy nuclei

Finally we demonstrate the applicability of the canonical-basis HFB method to nuclei heavier than ^{28}Si . We have encountered no special difficulties at least up to $A = 252$ except the increase in the computation time per gradient-method step.

For example, Fig. 11 shows the dependence of the average pairing gap Δ on the mass number A . In the cal-

FIG. 11: Dependence of the average pairing gap Δ on the mass number A . The strength of the pairing interaction is fixed at $v_p = -1000$ MeV fm³ while N_w is changed in two ways as shown in the legend.

culations, the normalization box is gradually expanded with increasing A : The edge of the box is at least 2.5 times as large as the liquid-drop-model diameter. We fix v_p at -1000 MeV fm³. Instead, we change N_w versus A .

When we assume a relation $4N_w = 2A$, we cannot reproduce the empirical trend that Δ is a decreasing function of A . We can improve the result by using different relations, e.g., $4N_w = A + 125$. However, the goal, a universal pairing force, should be more than an empirical formula expressing N_w as a function of A . It will be one of our future challenges.

VII. CONCLUSIONS

In this paper we have presented a method to obtain solutions of the HFB equation expressed in the canonical form, i.e. in terms of BCS-type wave functions, without using quasiparticle states. The method is fit to three-dimensional coordinate space representations and is advantageous to describe simultaneously arbitrary deformations, long and short density tails, and pairing correlations involving states in the continuum of the HF Hamiltonian.

We have improved the speed of the convergence to HFB solutions by a few orders of magnitude. For this purpose, we have modified the gradient method and derived the appropriate form of the Lagrange multiplier functionals for the orthogonality between canonical orbitals. The two-basis method has also been adapted by replacing the HF basis with the canonical basis to further speedup the convergence.

For delta-function pairing interactions, the wave functions of canonical orbitals have been shown to shrink infinitely into a spatial point once their occupation probabilities become less than some critical value. This problem is peculiar to the canonical-basis HFB method. To avoid it, a repulsive momentum dependent term has been added to the pairing interaction.

As a byproduct of the introduction of this term, the nature of high-lying canonical orbitals has been greatly clarified as approximate eigenstates of the pairing Hamiltonian. We have demonstrated that the level density and the spatial extent of high-lying canonical orbitals can be computed by applying the Thomas-Fermi approximation to the pairing Hamiltonian.

The obtained canonical orbitals have been examined in many aspects. One of the results is that canonical orbitals closer to the Fermi level have wave functions with longer tails. At very large radius, however, all the orbitals seem to change the slope of their tails to that of the orbital closest to the Fermi level. Another result is that quasiparticle states cannot be efficiently expanded in the canonical basis. Therefore the canonical orbitals perfectly describing the ground state are not sufficient to treat excitations.

The pairing force strength has been adjusted to reproduce the average pairing gap as a function of the number of canonical orbitals, which is used instead of an energy cut-off. Properties of the nucleus have been found to be almost independent of the number of canonical orbitals and rather insensitive to the relative strength of the momentum dependent to independent terms of the pairing force.

Although most of our discussions refer to calculations for ^{28}Si , we have also checked the applicability of the method to heavy nuclei up to $A=252$. Checks have also been done concerning the precision of the mesh representation in connection with this method.

We believe that the canonical-basis HFB method has the potential to become the standard approach to treat neutron-rich nuclei in HFB. As a next step, we are going to extend the formalism and the computer program concerning the treatment of $N \neq Z$ nuclei and the inclusion of the spin-orbit and the Coulomb interactions.

APPENDIX A: PRECISION OF THE MESH REPRESENTATION

In this Appendix, we examine the precision of the Cartesian mesh representation when it is applied to the canonical-basis HFB method. Discussions are given concerning the dependencies on i) the mesh spacing, ii) the approximation formulae for the derivatives, and iii) the size of the normalization box. The pairing force strength used is $v_p = -1032 \text{ MeV fm}^3$ with $N_w = 21$. The state is the prolate ground state of ^{28}Si .

i) We discuss the dependence on the mesh spacing a . For this purpose, we calculate the HF and HFB solutions for various value of a while keeping the size of the box constant. For the discrete approximation of the first and second derivatives, we use the 17-point formula [31]. According to the calculation using the finest mesh ($a = 0.3 \text{ fm}$), $E_{\text{tot}} = -257.723 \text{ MeV}$, $\Delta = 2.424 \text{ MeV}$, and $\beta = 0.3766$.

The mesh is changed in the following manner: We

FIG. 12: Errors of the total energy E_{tot} (top portion) and the quadrupole deformation parameter β (bottom portion) due to the finite mesh spacing a for the prolate solution of ^{28}Si . The result of HF (HFB) calculations are designated by triangles (circles) connected with dot (solid) lines. In the bottom portion, triangles and circles are open (solid) when the error is positive (negative).

use N_{mesh} mesh points in x , y , and z -directions. Then the length of the edge of the normalization box is $L = (N_{\text{mesh}} + 1)a$. We fix L at 24 fm so that increasing N_{mesh} from 15 to 79 corresponds to decreasing a from 1.5 fm to 0.3 fm. The error is defined as the deviation from the result with $a=0.3 \text{ fm}$. The center of mass of the nucleus is placed at the center of the box.

The top portion of Fig. 12 shows the error of the total energy E_{tot} as a function of the mesh spacing a . The error of the corresponding HF calculation is also shown for comparison. Before obtaining this result, we suspected that HFB solutions suffer from larger errors than HF solutions because the former involve states above the Fermi level while the latter depend on only levels below it. Higher levels contain more amount of high momentum components which are less accurately treated with a finite mesh spacing. However, this figure shows that the errors are of the same order. The principal reason may be that errors from high-lying levels are reduced by factors v_i^2 or $u_i v_i$.

The bottom portion of Fig. 12 shows the error of the quadrupole deformation parameter β . Unlike E_{tot} , the error of β takes both positive and negative values. For this quantity, the HFB errors are several times as large as the HF errors on the average. This may be related to

FIG. 13: Dependence of the error of the HFB total energy E_{tot} of ^{28}Si on the discrete approximation formulae used to evaluate the derivatives. Three curves correspond to different values of the mesh spacing a .

the strong influence of the pairing correlation on deformations.

ii) We compare some approximation formulae given in Ref. [31] for the evaluation of the derivatives. Note that the Fourier transformation method (or the Lagrange-mesh method [33] applied to uniform-spacing meshes) assumes a different boundary condition from the other formulae. It assumes the periodic boundary condition and the edge of the box is also slightly shortened to $N_{\text{mesh}}a$. The error is defined as the deviation from the most precise result, which is obtained with the 17-point formula and $a=0.3$ fm. We have not chosen the Fourier method for this purpose because of a large error due to numerical cancellations for more than several tens of mesh points.

In Fig. 13, the error of the total energy is shown for each approximation formula and for three values of the mesh spacing a . This figure tells, e.g., if one uses the 17-point formula with $a = 0.8$ fm for ^{28}Si , the error of the total energy is 70 keV.

One can observe two trends: First, for all the three mesh spacings, the error decreases as the formula involves more number of mesh points (Fourier transformation method uses all the mesh points in the box). Second, for every formula, the error decreases when the mesh spacing is decreased. Therefore, one can decrease the error of the total energy either by employing a more precise formula or by diminishing the mesh spacing.

On the other hand, the other quantities cannot always be improved significantly by using more precise formulae. For example, with $a=1.0$ fm, the error of the pairing gap Δ does not continue to decrease but seems to almost saturate around 10 keV for more than 9-point formulae (including the Fourier transformation). We have also found a similar saturation phenomenon in the error of the deformation parameter β , which is affected strongly by the pairing gap. The reason of this saturation is probably that the pairing gap is more sensitive than the total energy to high-lying states having large momentum and

FIG. 14: Errors of the total energy E_{tot} (on the left-hand side) and the r.m.s. mass radius r_{rms} (on the right-hand side) due to the finite box size L .

thus the lack of momentum larger than π/a in the mesh space becomes the main source of the error, while the change of the formulae can only improve the treatment of momentum components smaller than π/a .

iii) We examine the errors due to the finite size of the normalization box. We consider ^{28}Si , which has $\epsilon_F = -11.6$ MeV. Naturally the errors depend on the Fermi level. In this paper, however, we can treat only $N = Z$ nuclei, all of which have roughly the same Fermi level.

We control the size of the box L in terms of N_{mesh} while fixing a at 0.8 fm. We define the errors as the deviation from the result obtained with large L (~ 60 fm). Here, the comparison should be made within the same parity of N_{mesh} [34].

On the left- and right-hand sides of Fig. 14, we show the errors of the total energy E_{tot} and the r.m.s. radius, respectively. We have used $L = 24$ fm in most of the calculations shown in this paper. These figures confirm that this value of L leads to sufficiently precise results for both quantities. By comparing the errors of HF (crosses) and HFB (circles) solutions, one can see that the effects of the finite box size are of the same order between the two methods. This is because the density tail is determined by the Fermi level, which is roughly the same whether there exist pairing correlations or not.

APPENDIX B: THE MECHANISM OF THE COLLAPSE OF A HIGH-LYING CANONICAL ORBITAL INTO A SPATIAL POINT AND ITS REMEDIES

In this appendix we study the mechanism of “point collapse”, a phenomenon that the wave function of a canonical orbital shrinks infinitely into a point in the coordinate space once its occupation probability becomes less than some critical value. It is a problem peculiar to the canonical-basis HFB method. For this purpose, we consider only one canonical orbital explicitly while repre-

senting all the others in terms of uniform densities, ρ_0 , $\tilde{\rho}_0$, τ_0 , and $\tilde{\tau}_0$. The explicitly considered orbital is assumed to have a wave function whose spatial part is a Gaussian wave packet parameterized with a size parameter w as,

$$\psi_w(\mathbf{r}) = \left(\frac{2}{\pi}\right)^{3/4} w^{-3/2} e^{-(r/w)^2}. \quad (\text{B1})$$

The r.m.s. values of the coordinates and the wave numbers of this wave packet are, respectively, $\sqrt{\langle x^2 \rangle} = \sqrt{\langle y^2 \rangle} = \sqrt{\langle z^2 \rangle} = \frac{w}{2}$ and $\sqrt{\langle k_x^2 \rangle} = \sqrt{\langle k_y^2 \rangle} = \sqrt{\langle k_z^2 \rangle} = \frac{1}{w}$. One can express the densities of the total system as,

$$\rho = \rho_0 + \rho_1, \quad \rho_1 = 4v^2 |\psi_w(\mathbf{r})|^2, \quad (\text{B2})$$

$$\tau = \tau_0 + \tau_1, \quad \tau_1 = 4v^2 |\nabla \psi_w(\mathbf{r})|^2, \quad (\text{B3})$$

$$\tilde{\rho} = \tilde{\rho}_0 + \tilde{\rho}_1, \quad \tilde{\rho}_1 = 4uv |\psi_w(\mathbf{r})|^2, \quad (\text{B4})$$

$$\tilde{\tau} = \tilde{\tau}_0 + \tilde{\tau}_1, \quad \tilde{\tau}_1 = 4uv |\nabla \psi_w(\mathbf{r})|^2, \quad (\text{B5})$$

where v^2 is the occupation probability of this orbital and $u = \sqrt{1 - v^2}$.

The change in the total energy due to the presence of the explicitly considered orbital is given by

$$\Delta E_{\text{tot}} = 4\pi \int_0^\infty [\mathcal{H}(r) - \mathcal{H}_0(r)] r^2 dr, \quad (\text{B6})$$

where $\mathcal{H}$ has been defined by Eq. (23), while $\mathcal{H}_0$ by replacing ρ , τ , $\tilde{\rho}$, and $\tilde{\tau}$ in the equation with ρ_0 , τ_0 , $\tilde{\rho}_0$, and $\tilde{\tau}_0$, respectively. For $k_c = \tilde{\rho}_c = \infty$, one can obtain the following expression for ΔE_{tot} ($\alpha = 1$ is assumed for the density dependence of the Skyrme force):

$$\begin{aligned} \Delta E_{\text{tot}} = & C_1 uv + C_2 v^2 + C_3 \frac{v^2}{w^2} + C_4 \frac{u^2 v^2}{w^3} + C_5 \frac{uv^3}{w^3} \\ & + C_6 \frac{v^4}{w^3} + C_7 \frac{v^4}{w^5} + C_8 \frac{u^2 v^4}{w^6} + C_9 \frac{v^6}{w^6}, \end{aligned} \quad (\text{B7})$$

where

$$\begin{aligned} C_1 &= v_p \left(1 - \frac{\rho_0}{\rho_c}\right) \tilde{\rho}_0, \\ C_2 &= 4 \left(f_1 \tau_0 + \frac{3}{4} t_0 \rho_0 + \frac{3}{16} t_3 \rho_0^2 - \frac{v_p}{8 \rho_c} \tilde{\rho}_0^2 \right), \\ C_3 &= 12 \left(\frac{\hbar^2}{2m} + f_1 \rho_0 \right), \\ C_4 &= \frac{2}{(\sqrt{\pi})^3} v_p \left(1 - \frac{\rho_0}{\rho_c}\right), \\ C_5 &= -\frac{4}{(\sqrt{\pi})^3} v_p \frac{\tilde{\rho}_0}{\rho_c}, \\ C_6 &= \frac{3}{(\sqrt{\pi})^3} (2t_0 + t_3 \rho_0), \\ C_7 &= \frac{24}{(\sqrt{\pi})^3} (f_1 - 4f_2), \\ C_8 &= -\frac{64}{(\sqrt{3}\pi)^3} \frac{v_p}{\rho_c}, \\ C_9 &= \frac{32}{(\sqrt{3}\pi)^3} t_3. \end{aligned}$$

FIG. 15: Change in the total energy ΔE_{tot} due to the addition of a canonical orbital with occupation probability v^2 whose wave function is a Gaussian wave packet parameterized with a width parameter w . ΔE_{tot} is plotted versus w for several values of v^2 . Local maxima and minima of the curves are designated with circles and crosses, respectively.

Among the nine coefficients, C_1, C_2, C_4 , and C_6 are negative (at low density places) while the others are positive.

Fig. 15 shows ΔE_{tot} as a function of w for several values of v^2 . In the calculations, we employ a pairing force having $v_p = -450 \text{ MeV fm}^3$, $\rho_c = 0.32 \text{ fm}^{-3}$, and $\tilde{\rho}_c = k_c = \infty$. This strength v_p would give $\Delta = 2 \text{ MeV}$ for $A = 28$ system with $N_w = 21$ if point collapses would not occur. The effects of the momentum and the pairing density dependent forces are discussed later. The mean-field force is SIII without the spin-orbit term. $A = \infty$ is used in Eq. (21) for the nucleon reduced mass. For the background densities, we employ $\rho_0 = \tilde{\rho}_0 = 1 \times 10^{-3} \text{ fm}^{-3}$ and $\tau_0 = \tilde{\tau}_0 = 3.6 \times 10^{-5} \text{ fm}^{-5}$, which are typical values at peripheral regions where point collapses occur in actual HFB calculations for finite nuclei. (A Fermi gas relation $\tau = \frac{3}{5} \left(\frac{3\pi^2}{2}\right)^{2/3} \rho^{5/3}$ is assumed to determine τ from ρ .)

One can see from Fig. 15 that the total energy becomes minimum at the bottom of a dip for small values of v^2 . The dip emerges at $w = 0.7 \text{ fm}$ when $v^2 = 6.7 \times 10^{-3}$ and, as v^2 is decreased, its depth increases while the location of the bottom moves to smaller values of w .

This minimum in the dip corresponds to HFB “solutions” in finite nuclei reported in Refs. [13, 14], in which the wave function of a high-lying orbital has shrunk into a mesh point. HFB states having physically reasonable wave functions turn themselves into such strange states in the following abrupt way: In the course of gradient-method evolutions, suddenly after an almost stationary situation has continued, ϵ of a high-lying orbital soars up to a few hundred MeV and simultaneously the total energy decreases by a few MeV.

The dip is caused by the zero-rangeness of the pairing force and thus does not correspond to physically meaningful states. Physical solutions should be found at $w > 6 \text{ fm}$, where ΔE_{tot} is slightly negative. Therefore one needs to eliminate the effects of such dips in order to obtain well-behaving HFB solutions in the canonical-basis representation.

It is worth pointing out here that a wave packet with $w=0.3$ fm can be expressed fairly precisely on a mesh with spacing $a=0.8$ fm. It is because the maximum wave number expressible with the mesh is $\frac{\pi}{a}$ and thus the minimum size of the wave packet of Eq. (B1) can be estimated roughly by a relation $\sqrt{\langle k_x^2 \rangle} = \frac{1}{w} \sim \frac{\pi}{a}$, which leads to $w \sim \frac{a}{\pi} = 0.26$ fm for $a=0.8$ fm. Therefore collapses to wave packets as small as $w = 0.3$ fm are a practical problem even when $a=0.8$ fm.

Before discussing how to remove the dip, let us clarify in an analytical way the mechanism which gives rise to the dip. We consider the limit of $v^2, w \rightarrow 0$, in which the nature of the dip becomes most manifest. Therefore, the following considerations are for the untruncated Hilbert space, not for mesh representations.

In order to study this limit, we assume a scaling behavior $v = \mu w^\nu$ where w is the location of the bottom of the dip. μ and ν are positive constants to be determined. One can easily confirm that, for $\nu > \frac{3}{2}$, all the nine terms in the right-hand side of Eq. (B7) have positive powers of w and thus converge to zero as $w \rightarrow 0$. Consequently, it must be satisfied that $\nu \leq \frac{3}{2}$ for a point-collapse solution to exist. For $0 < \nu < \frac{3}{2}$, $\Delta E_{\text{tot}} = C_8 \mu^4 (\frac{1}{w})^{6-4\nu} +$ (lower order terms in $\frac{1}{w}$) and thus the energy diverges to $+\infty$ as $w \rightarrow 0$. The only possibility for a point-collapse solution to exist is in the case of $\nu = \frac{3}{2}$, for which $\Delta E_{\text{tot}} = C_4 \mu^2 + C_8 \mu^4 +$ (terms with positive powers in w). From a condition $\partial \Delta E_{\text{tot}} / \partial \mu = 0$, one immediately finds that ΔE_{tot} becomes minimum at $\mu^2 = -C_4 / 2C_8$. The minimum value in the limit $w \rightarrow 0$ becomes

$$\Delta E_{\text{tot}} = -\frac{(C_4)^2}{4C_8} = \frac{(\sqrt{3})^3}{64} v_p \rho_c \left(1 - \frac{\rho}{\rho_c}\right)^2. \quad (\text{B8})$$

Its numerical value is -11.7 MeV for the parameters used. The essential points clarified here are i) the minimum of the total energy is realized in the limit $v, w \rightarrow 0$ with $v \propto w^{3/2}$ and ii) the limiting value of the minimum energy is finite.

One can also derive analytically the location w of the barrier top which divides the physical and unphysical regions. From the condition,

$$\frac{\partial \Delta E_{\text{tot}}}{\partial w} = -2C_3 \frac{v^2}{w^3} - 3C_4 \frac{u^2 v^2}{w^4} + \mathcal{O}(v^3) = 0, \quad (\text{B9})$$

one can simply obtain the location of the local maximum as,

$$w = -\frac{3C_4}{2C_3} = -\frac{v_p \left(1 - \frac{\rho_0}{\rho_c}\right)}{4(\sqrt{\pi})^3 \left(\frac{\hbar^2}{2m} + f_1 \rho_0\right)}, \quad (\text{B10})$$

by neglecting terms of $\mathcal{O}(v^3)$. Note that it is independent of v (if v is sufficiently small). With the parameters used, $w = 1.0$ fm. Indeed in Fig. 15, the location of the top of the barrier (designated with open circles) seems to converge to ~ 1 fm as v^2 is decreased. The height of the

FIG. 16: Effects of changing k_c on the total energy ΔE_{tot} (left-hand portion) and on the width parameter w of the added orbital at local minimum and maximum of ΔE_{tot} . The dot, triple-dot-dash, dot-dash, dash, and solid curves are obtained with $k_c = 15, 30, 100, 500$, and ∞ (fm^{-1}), respectively. The other parameters of the model are the same as those used for Fig. 15.

maximum is $C_1 v + \mathcal{O}(v^2)$, which is $\mathcal{O}(v)$ and converges to zero as $v \rightarrow 0$. Therefore, for sufficiently small values of v , HFB solutions easily fall into the unphysical dip since the mesh spacing is much smaller than 1.0π fm.

Now, we examine two types of pairing interactions which can remove the unphysical dip.

The first type of the interaction is the momentum dependent term of Eq. (19). With $k_c < \infty$, but with $\tilde{\rho}_c = \infty$, ΔE_{tot} becomes to have additional terms as,

$$\Delta E'_{\text{tot}} = \Delta E_{\text{tot}} + C_{10} uv + C_{11} \frac{uv}{w^2} + C_{12} \frac{u^2 v^2}{w^5}, \quad (\text{B11})$$

where ΔE_{tot} is given by Eq. (B7) and,

$$\begin{aligned} C_{10} &= -\frac{v_p}{2k_c^2} \tilde{\tau}_0, \\ C_{11} &= -\frac{v_p}{2k_c^2} 3\tilde{\rho}_0, \\ C_{12} &= -\frac{v_p}{2k_c^2} \frac{30}{(\sqrt{\pi})^3}. \end{aligned}$$

Since $v_p < 0$, C_{10} , C_{11} , and C_{12} are positive. The dominant term in the limit $w \rightarrow 0$ is the one having coefficient C_{11} (C_{12}) for $\nu > (<) 3$, which behaves as $\mu w^{\nu-2}$ ($\mu^2 w^{2\nu-5}$). These two terms overwhelm the negative terms in ΔE_{tot} . Consequently wave functions cannot shrink to a point.

However, a dip can still emerge with finite v . Figure 16 shows how the local minimum (the bottom of the dip) and the local maximum (the top of the barrier) of ΔE_{tot} change versus v^2 . The left-hand portion shows the depth and the height (ΔE_{tot}), while the right-hand portion shows the locations (w).

The solid curves are obtained with $k_c = \infty$. The upper solid curve stands for the height of the local maximum, which converges to zero as $v^2 \rightarrow 0$, as already discussed analytically. (This curve is almost unchanged when k_c

is decreased to finite values.) The lower solid curve corresponds to the depth of the local minimum, which converges to -11.7 MeV, in accord with Eq. (B8).

With finite values of k_c , the minimum becomes shallower as v^2 is decreased and it disappears at some small value of v^2 . This disappearance is clearly seen in the dot curve (corresponding to $k_c=15$ fm $^{-1}$) in the right-hand portion of the figure. A numerical search has shown that the dip exists only for $k_c > 10$ fm $^{-1}$.

The result with this simplified model roughly agrees with realistic HFB calculations: We have observed that point collapses can occur for $k_c > 6$ fm $^{-1}$ in calculations like those shown in Fig. 7. The difference between 6 fm $^{-1}$ and 10 fm $^{-1}$ can be partially attributed to the finite-point approximation to the derivatives, which underestimates the kinetic energy by 30% at $k = \frac{\pi}{a}$, as shown in Fig. 20 of Ref. [31].

Incidentally, the requirement of orthogonality among the canonical orbitals does not seem to change the conclusion drawn with this model. The first reason is that point collapses in light nuclei are not affected by orthogonality if the number of canonical orbitals N_w is relatively small. This is because of the symmetry (e.g., D_{2h}) of the solution: If a high-lying orbital is the only one in an irreducible representation of the symmetry (e.g., in $P_x=-$ sector when x -axis is the shortest axis), it is automatically orthogonal to the other orbitals. In this case, it shrinks not to a point but to many points (e.g., two points at $x = \pm R$, $y = z = 0$, $R \sim$ nuclear radius, with opposite-sign amplitudes). Indeed, we have experienced that point collapses occur only when N_w is small for relatively small values of k_c . The second reason is an empirical fact that, with large values of k_c , many orbitals collapse one after another or simultaneously even for large N_w : The process of point collapses under orthogonality condition may not be so complicated as it sounds in such cases.

The second type of the interaction we examine is the pairing density dependent term of Eq. (19). With $\tilde{\rho}_c < \infty$, but with $k_c = \infty$, ΔE_{tot} has additional terms of Eq. (B7) as,

$$\Delta E''_{\text{tot}} = \Delta E_{\text{tot}} + C_{13}uv + C_{14}\frac{u^2v^2}{w^3} + C_{15}\frac{u^3v^3}{w^6} + C_{16}\frac{u^4v^4}{w^9}, \quad (\text{B12})$$

where

$$\begin{aligned} C_{13} &= -\frac{2v_p}{\tilde{\rho}_c^2}\tilde{\rho}_0^3, \\ C_{14} &= -\frac{2v_p}{\tilde{\rho}_c^2}\frac{6}{(\sqrt{\pi})^3}\tilde{\rho}_0^2, \\ C_{15} &= -\frac{2v_p}{\tilde{\rho}_c^2}\frac{128}{(\sqrt{3\pi})^3}\tilde{\rho}_0, \\ C_{16} &= -\frac{2v_p}{\tilde{\rho}_c^2}\frac{64}{\sqrt{2\pi^9}}. \end{aligned}$$

All the added terms are positive. Assuming $v = \mu w^\nu$, terms with coefficients C_{15} and C_{16} have negative powers

FIG. 17: Same as in Fig. 16, but for the effects of $\tilde{\rho}_c$. The dot, triple-dot-dash, dot-dash, dash, and solid lines are obtained with $\tilde{\rho}_c = 1.5, 6, 25, 100$, and ∞ (fm $^{-3}$), respectively. The other parameters of the model are the same as those used for Fig. 15.

of w at $\nu = \frac{3}{2}$. Consequently point collapses can be avoided by using finite values of $\tilde{\rho}_c$.

Figure 17 shows extrema of ΔE_{tot} versus v^2 . The solid curve corresponds to $\tilde{\rho}_c = \infty$ and is the same as that in Fig. 16. The other types of curves are for finite values of $\tilde{\rho}_c$. One can see that ΔE_{tot} at the local minimum is already very small with $\tilde{\rho}_c = 1.5$ fm $^{-3}$ (dot curve), which is much larger than the typical values of $\tilde{\rho}$ and thus leads to only physically acceptable small amount of modification of the pairing interaction. This figure is consistent with the results of actual HFB calculations: From Fig. 4 of Ref. [14], one can see that point collapses can be avoided with $\tilde{\rho}_c < 1.0$ fm $^{-3}$.

Mathematically speaking, however, the local minimum continues to exist for arbitrary v , which is a different behavior from that with finite k_c . In the limit of $v \rightarrow 0$, this minimum behaves as $w \rightarrow 0$ and $\Delta E''_{\text{tot}} \rightarrow -0$. Because the depth converges to zero from below, the point-collapse limit is unstable and is not very meaningful. So, let us give only briefly the result of an analytical consideration. Assuming $v = \mu w^\nu$, one can show that the local minimum continues to exist in the limit $w \rightarrow 0$ with $\nu = 3$ and μ determined by a cubic equation $C_1 + C_{13} + 2C_4\mu + 4C_{16}\mu^3 = 0$ if $C_1 + C_{13} < 0$ (i.e., $\tilde{\rho}_c > \sqrt{2}\tilde{\rho}_0$ for $\rho_0 \ll \rho_c$). At the local minimum, $\Delta E''_{\text{tot}} \propto v$ and $w \propto v^{1/3}$. One can see this scaling behavior with $\nu = 3$ on the right-hand side of Fig. 17.

In the present paper we have used the momentum dependent interaction because it has a physical origin, i.e., the finite-rangeness. However, the pairing density dependent interaction may also be useful under different circumstances because the momentum dependent interaction leads to a divergence of the pairing energy in unrestricted Hilbert space [22]: The assumption of $uv \geq 0$ made in this paper is not adequate for orbitals with $k > k_c$.

To summarize, assuming a wave function of Gaussian form, we have clarified the mechanism of the point-collapse phenomenon occurring in the canonical-basis HFB method due to delta interactions. We have also

demonstrated the successes of momentum or pairing density dependent interactions in avoiding the collapse.
